
Springer Handbook of Nanomaterials

Springer Handbook provides a concise compilation of approved key information on methods of research, general principles, and functional relationships in physical and applied sciences. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of scientific and technical information.

The volumes are designed to be useful as readable desk reference book to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

Foreword

Nanomaterials are based on structures with characteristic features on the scale of nanometers. This size is small if we compare with normal things around us, but it is not particularly small on the atomic scale. In fact, distances between individual atoms are typically a tenth of a nanometer (an Ångström), so a piece of a material with a side of a nanometer may contain hundreds or even a thousand atoms. Therefore a nanomaterial usually has some resemblance to a bulk material based on the same atoms, but the normal material has been modified to reach superior properties such as higher mechanical strength, different optical and magnetic performance, permeability to a fluid, or something else. Thus nanomaterials may allow us to obtain properties that were previously impossible to achieve, impractical to manufacture, or too expensive for use on a scale large enough to be significant in daily life.

Among the general public, and even the scientific community, nanomaterials are widely perceived as *new* in many different way – newly invented, newly used by human cultures, and newly studied.

In fact, nanomaterials are not new at all. Nature itself is filled with nanofeatures that have evolved in biological systems, one well known example being moths' eyes with nanostructured surfaces that provide antireflection and allow efficient use of feeble light.

Looking at history, we can also see that human beings have been using nanomaterials of various sorts for a very long time. Let us take three examples: nanocarbons, nanometals, and nanoceramics.

Nanocarbons can be created in abundance on the nanometer scale when organic matter burns. Such carbon nanoparticles were used by humans as far back as forty thousand years ago to depict and decorate. The particles were mixed with fat and used for painting in the caves of Altamira and Lascaux in Spain and France, to mention two especially striking and well known cases. This kind of carbon, in principle, is also an essential ingredient in ink and printing paste, and it was used by monastic scribes and by Gutenberg and his followers to make texts of explosive cultural significance and stunning beauty.

Nanometals have also been utilized for thousands of years. An example is the world famous Lycurgus glass cup, now in the holdings of the British Museum. This

cup, which was probably created in Rome during the 4th century AD, contains embedded nanoparticles of gold and silver. Because of these particles, the cup normally seems to be a light green color, but it becomes ruby red when light is shone through it. The Lycurgus cup is a wonder of craftsmanship from Antiquity, and it is based on nanotechnology.

Finally, let's consider *nanoceramics*. The world's most widely used artificial material is the nanoceramic cement, which was used extensively by the Romans in constructing buildings, baths and aqueducts. Furthermore, recent archaeological discoveries indicate that the Romans were not the first, that the Macedonians were using cement centuries earlier.

Even research on nanomaterials is not as new as it seems. The term apparently began appearing in the titles of scientific publications only 15 years ago. But today's *nano* was the subject of an older literature under the term *ultrafine*.

As the examples above indicate, nanomaterials are well rooted in the past. But they are also very much of the future. Let us consider a few specific examples.

Nanocarbons, used for cave painting and the printing of the Gutenberg Bible, are very much in focus today, in the forms of fullerenes, nanotubes and nanodiamonds, all of which offer a multitude of possibilities for future technology. Two-dimensional carbon in the form of graphene has unique properties directly based on quantum physics, and it may have important applications in transparent electronics and elsewhere. Graphane, its hydrogenated cousin, is exciting in its own right.

Nanometals, employed by the Romans to create the amazing Lycurgus glass cup, are the basis today for manifold applications, including thermal collectors that harness the sun's energy and innovative *plasmonic* solar cells. Indeed, *plasmonics* is becoming a household word because of its relevance for light-emitting diodes, sen-

Prof. Claes-Göran Granqvist

Department of
Engineering Sciences
Solid State Physics
Uppsala University
Sweden

sors and catalysts for chemical reactions, just to mention a few technologies.

Thus many aspects of nanomaterials are indeed truly new and are the subject of intense worldwide interest in today's academic and industrial research laboratories. This *Handbook*, which is a testimony to this growing body of knowledge, presents welcome and authoritative surveys over nanocarbons, nanometals and nanoceramics in its first three parts. Other sections cover nanocomposites and nanoporous materials, as well as organic and biological nanomaterials. Applications and impacts are discussed at the end, together with important questions of toxicology, hazards and safety. These

issues are of great importance. We should remember the terrible impact that asbestos – in fact, a natural nanomaterial – had on human health before it was widely banned. We certainly do not want to discover one day that, in our quest for new materials to solve technological problems, we have unleashed another dangerous nanomaterial into the world.

The editor and authors are to be congratulated on the successful completion of this *Handbook of Nanomaterials*. It will surely be a work of great and lasting importance for the scientific community.

Uppsala, November 2012 Prof. Claes G. Granqvist

Foreword

It has been more than a decade since President Bill Clinton talked about the promise of nanotechnology and the importance of increasing investments in nanoscale science and engineering research in a speech at the California Institute of Technology on January 21, 2000. In his remarks, the President recalled Richard Feynman's American Physical Society talk there in 1959. The following week, in his State of the Union Address, President Clinton announced his *21st Century Research Fund*, a \$3 billion budget increase, which included the multiagency national nanotechnology initiative (NNI). The first year's budget allocation to NNI was close to half a billion US\$, nearly doubling what the agencies had been spending on nanoscale research; and with the continuous support of succeeding administrations the budget quadrupled in a decade. This strong federal support, initially based on the promise of a revolutionary new technology, was justified by steady scientific and technological advances at the nanometer scale and by the growth of commercial applications, especially in biotechnology and nanoelectronics, offering new ways to tackle disease and new industrial tools and toys. As President Clinton's former science advisor, I am confident that he is as pleased with the progress in nanotechnology as are all of us – inside and outside government – who worked with him to develop and implement the NNI.

One way to define nanotechnology, perhaps, is that it is the knowledge and engineering (design and control) of physical, chemical, and biological systems at the nanometer (10^{-9} m) scale – from the size of individual molecules to dimensions of the order 100 nm. Nanotechnology is, by its nature, a field of synthesis and synergy often requiring physics, chemistry, biology, and almost all areas of engineering in the performance of research and engineering design, for example inventing and optimizing the tools needed to synthesize and manipulate matter at the nanometer scale. As with other new fields, rapid advances in nanotechnology have led to specialization into subdisciplines, one of the most natural and important being *nanomaterials*.

Nanomaterials science and engineering includes the production, properties, and applications of materials at the nanometer scale; it is a part of nanotechnology and at the same time, evidently, a subfield of materials

science. The main goal of materials science – macroscopic and nanoscale – is providing new and improved building blocks for engineers in all fields. That said, *nanomaterials* science has distinct features compared to the more mature science and engineering of macroscopic materials, the most salient being its revolutionary nature. New materials and groups of materials with surprising properties continue to be discovered – graphene and topological insulators are two examples from the recent past. As with all exploration at the frontiers of knowledge, it is impossible to predict what discoveries will be made or how those discoveries might lead to applications, commercial or otherwise. But the history of science and technology suggests that some of those advances will surpass all our expectations. Already we are seeing the benefits of nanotechnology in computers and telecommunication devices, computer chips and sensors in automobiles, electric car batteries, medicines and sun creams, tablecloths and socks, tennis rackets, boats, golf clubs – and more. Given the likelihood that ongoing research will yield many more *nanomaterials*, with surprising properties and, at the same time, the continued exponential growth in the number of applications, it seems clear that *nanomaterials* will, at some level, transform most aspects of our lives. It is not too much of a stretch to suggest that President Clinton's policy decision to set up the NNI, which has supported thousands of scientists and engineers working in the field, has indeed helped move us closer to realizing Feynman's prediction – or, perhaps we should say his vision – of a revolutionary new technology. In the world of *nanomaterials* there is still *plenty of room at the bottom* to use Richard Feynman's famous words.

A handbook, by one definition, is a compilation of knowledge about a particular field, collected into a single volume publication that is convenient to use as

Prof. Neal Lane

Malcolm Gillis University
Professor,
Department of Physics
and Astronomy,
Senior Fellow,
James A. Baker III Institute
for Public Policy
Rice University
Houston, Texas

a ready reference. Since *nanomaterials* science can now be considered a self-sufficient discipline, a handbook is appropriate and timely. This new *Springer Handbook of Nanomaterials* targets several audiences: researchers working in industry or academia, as well as graduate students studying related fields. The organization of the book follows the usual classification scheme of macroscopic materials science, with information of a materials group – e.g., metals – collected together;

other aspects can be followed easily by using the well-developed index.

Putting together a handbook in a new field is a formidable challenge. I would like to congratulate the editor and all of the authors who collaborated to plan, collect materials, and write this important groundbreaking *Springer Handbook of Nanomaterials*.

Houston, January 2013

Neal Lane

Preface

Those who control materials, control technology, stated Eiji Kobayashi, Senior Advisor of Panasonic Corporation, explaining the importance of materials science and engineering. I would translate this quote to *those who control nanomaterials control nanotechnology*; and, considering the effect of the development of nanomaterials and nanotechnology on our global infrastructure, it is not too bold to state that those control technology at large, too. Nanomaterials have a determinant role in many of advanced products around us. Stamp-sized sound recording devices, modern passenger and fighter jets, spaceships and space stations, extreme tall buildings and long bridges, none of these could be created without these marvelous materials. As one could not foresee 50 years ago, the fast development that provided the opportunity for these objects to be realized, now we cannot imagine our life without them.

The editor considers materials science as the knowledge of structure; properties of materials predicted or explained with the help of this knowledge; experimental and theoretical tools designed and established for preparing, characterizing and modifying processes, and last but not least showing application possibilities of the resulted materials. After defining nanomaterials we can simply transpose this description for nanomaterials science. Materials are considered *nanomaterials* when their structure, processing, characterization or application differ from the macroscopic materials and this difference relates to the – normally sub-100 nm – feature size. The *description* of the nanomaterials in this Springer Handbook follows the thorough but concise explanation of the synergy of structure, properties, processing, and applications. Specifically, our aim was to point out the distinction between the properties of bulk and nanomaterials and the reasons for these differences.

To fulfill these goals, we provide a balanced report of the literature of each materials group. The format follows the well-established structure of the Springer Handbooks with chapters as the basic units that are organized into several groups. In each chapter, authors cover materials of their expertise, however, they focus not only on their own work, but report the interesting and important efforts in the community, establishing

a balance between references and scientific results reported in tables and figures. We describe nanomaterials in textbook style for newcomers, encyclopedia-like elements and – to follow the fast-space of new results – review or research papers for the experienced reader. Beyond scientific and moral correctness we also look for clarity by concise and easy-to-follow text, well-designed and clear figures which were all professionally drawn by graphics designers.

The book is divided in Parts A to G and covers carbon-based nanomaterials: fullerenes, nanotubes, nanofibers and nanodiamond, noble and common metals and alloys, ceramic materials, crystalline and glassy oxides and other compounds; composites, hybrid structures and solutions as well as porous metals, ceramics and silicon; organic and bio-nanomaterials, bones and fibers and select applications, respectively. This higher level structure conforms to the macroscopic classification of materials and it is composed of chapters. Each chapter is self-consistent and builds up of similar parts, history, definitions, production of the given materials, properties, and applications. All of these parts are richly illustrated and consist of a balanced ratio of important basics and recent results.

My pleasant obligation is to thank all of the help I received in planning and implementing the handbook. First of all, I need to acknowledge the diligent work of the authors in developing the chapters which involves more effort than a review paper, and the reward is not so immediate and evident. Their expertise, energy and time are greatly appreciated. I also would like to thank the advices and help of my colleagues at Rice University and at Rensselaer Polytechnic Institute; as well as Professors Thomas F. George, Bob Curl, Phaedon Avouris, Li Song and Jinqian Wei for keeping contact with many authors. The great workmanship of the Springer publishing team and the continuous support of the managing editors Mayra Castro and Werner Skolaut are also appreciated. I also need to thank my colleagues and friends, Laszlo B. Kish, Claes-Goran Granqvist, Pulickel M. Ajayan and Richard W. Siegel that the collaboration with them oriented me to nanomaterials science. Last, but not least, I thank for the help and pa-

tience of my wife, Agnes, without her I would have not been able to finish this job.

I wish the reader a pleasant and beneficial time when using the Springer Handbook of Nanomaterials, and

I hope that it serves as a frequently opened reference work.

Houston, November 2012

Robert Vajtai

About the Editor

Robert Vajtai is a Faculty Fellow at Rice University, Houston, Texas, in the Department of Mechanical Engineering and Materials Science. His expertise covers synthesis, processing, characterization of physical and chemical properties of new, advanced material forms and structures. More specifically Dr. Vajtai's interests are in nanostructured materials, nanocomposites and nanomaterials; as well as their applications in thermal management, energy storage, microelectromechanical systems, sensors and electronic devices.

Dr. Vajtai received his scientific education in physics and his Ph.D. degree in solid-state physics from the University of Szeged (then named Jozsef Attila University), Hungary. From 1987 to 2002 he was a faculty member of the Department of Experimental Physics at the University of Szeged, Hungary. He was rewarded by the Bolyai Fellowship of the Hungarian Academy of Sciences for 1999-2000. He spent sabbaticals as a Fellow of the Swedish Institute in The

glosseintragAAngstrom Laboratory in Uppsala, Sweden, in the years 1998 and 1999; as an Eötvös Fellow at the EPFL in Lausanne, Switzerland in 1995/1996 and visited the Max Planck Institute in Göttingen, Germany, in 1993 via a Max Planck Fellowship. Before moving to Rice University in 2008, Dr. Vajtai spent eight years at the Rensselaer Polytechnic Institute, Troy, New York, where he was a Laboratory Manager at the Rensselaer Nanotechnology Center managing the carbon nanotechnology laboratories.

Dr. Vajtai started his research as a physicist studying laser-metal interaction, melting and oxidation of refractive metals and the nonlinear behavior of the far-from equilibrium processes and systems. Later he developed methods for pulse-probe spectroscopy of biomaterials as well as OH radicals used for the study of organic contamination of the atmosphere by airborne LIDAR systems. His research in materials science started with the synthesis of nanometals and nanosized oxides for the development of sensors. This lead to a new method for the preparation of germanium nanoparticles for building inverse opals used in infrared optical sensing. His most significant contribution is related to the synthesis of different forms of nanocarbons such as carbon nanotubes, graphene and macroscopic systems designed and built from these carbon allotropes, e.g., electromechanical parts and nanotube wires. Recently, his interest extended to various atomically thin layers, hexagonal boron nitride, transition-metal dichalcogenides and oxides.

He has more than 145 journal publications in peer reviewed scientific journals and he delivered numerous invited, keynote and plenary lectures on the topic.

Dr. Vajtai is a passionate teacher, he lectured physics, thermodynamics and electrodynamics courses with hundreds of experimental demonstrations; introductory and advanced courses of materials science. He received several mentoring awards, among those the Siemens-Westinghouse Mentoring Award.

Robert Vajtai is a Faculty Fellow in the Department of Mechanical Engineering & Materials Science at Rice University. He received his undergraduate and Ph.D. degrees from the University of Szeged, then named Jozsef Attila University, Hungary.

Contents

Foreword by Claes-Göran Granqvist	V
Foreword by Neal Lane	VII
List of Abbreviations	XXIX

1 Science and Engineering of Nanomaterials

<i>Robert Vajtai</i>	1
1.1 History and Definition of Nanomaterials.....	2
1.2 Formation of Nanomaterials	6
1.3 Properties of Nanomaterials.....	10
1.4 Typical Applications of Nanomaterials	22
1.5 Concluding Remarks	31
1.6 About the Contents of the Handbook	31
References	31

Part A NanoCarbons

2 Graphene – Properties and Characterization

<i>Aravind Vijayaraghavan</i>	39
2.1 Methods of Production	42
2.2 Properties	50
2.3 Characterization	58
2.4 Applications.....	69
2.5 Conclusions and Outlook.....	74
References	74

3 Fullerenes and Beyond: Complexity, Morphology, and Functionality in Closed Carbon Nanostructures

<i>Humberto Terrones</i>	83
3.1 Geometry and Structural Features of Fullerenes	85
3.2 Methods of Synthesis of Fullerenes and Proposed Growth Models....	88
3.3 Physicochemical Properties of Fullerenes.....	90
3.4 Applications of Fullerenes and Beyond	92
3.5 Conclusions.....	99
References	99

4 Single-Walled Carbon Nanotubes

<i>Sebastien Nanot, Nicholas A. Thompson, Ji-Hee Kim, Xuan Wang, William D. Rice, Erik H. Hároz, Yogeeswaran Ganesan, Cary L. Pint, Junichiro Kono</i>	105
4.1 History.....	106
4.2 Crystallographic and Electronic Structure	106

4.3	Synthesis	111
4.4	Optical Properties	115
4.5	Transport Properties	123
4.6	Thermal and Mechanical Properties	128
4.7	Concluding Remarks	135
	References	135
5	Multi-Walled Carbon Nanotubes	
	<i>Ákos Kukovecz, Gábor Kozma, Zoltán Kónya</i>	147
5.1	Synthesis	148
5.2	Chemistry of MWCNTs	153
5.3	Properties	157
5.4	Selected Applications	163
	References	169
6	Modified Carbon Nanotubes	
	<i>Aarón Morelos-Gómez, Ferdinando Tristán López, Rodolfo Cruz-Silva, Sofia M. Vega Díaz, Mauricio Terrones</i>	189
6.1	Doped Carbon Nanotubes	191
6.2	Defects in Carbon Nanotubes	193
6.3	Nanotube Chemical Functionalization	197
6.4	Properties of Modified Carbon Nanotubes	203
6.5	Characterization of Modified Carbon Nanotubes	208
6.6	Applications of Modified Carbon Nanotubes	215
6.7	Toxicity and Biocompatibility	218
6.8	Conclusions	220
6.9	Outlook and Perspectives	221
	References	221
7	Carbon Nanofibers	
	<i>Yoong A. Kim, Takuya Hayashi, Morinobu Endo, Mildred S. Dresselhaus</i>	233
7.1	Similarity and Difference Between Carbon Fibers and Carbon Nanofibers	234
7.2	Growth and Structural Modifications of Carbon Nanofibers	238
7.3	Applications of Carbon Nanofibers	251
7.4	Conclusions	257
	References	258
8	Nanodiamonds	
	<i>Olga A. Shenderova, Suzanne A. Ciftan Hens</i>	263
8.1	Stability of Diamond at the Nanoscale	264
8.2	Types of Nanodiamonds and Methods of Nanodiamond Synthesis ...	267
8.3	Detonation Nanodiamond Processing and Modification	278
8.4	Fluorescent Nanodiamonds	284

8.5	Applications of Nanodiamond Particles	285
8.6	Future Directions of Production and Applications	292
	References	293

Part B NanoMetals

9 Noble Metal Nanoparticles

	<i>Theruvakkattil S. Sreeprasad, Thalappil Pradeep</i>	303
9.1	Historical Perspective of Gold and Silver NPs	304
9.2	Diverse Nanostructures	307
9.3	Common Synthetic Routes for the Preparation of Noble Metal NPs	311
9.4	Properties of Noble Metal Nanoparticles	322
9.5	Postsynthetic Tuning of Properties	324
9.6	Functionalized Metal NPs	343
9.7	Applications of Gold and Silver Nanoparticles	347
9.8	New Gold and Silver Materials – Quantum Clusters	363
9.9	Conclusions	366
	References	367

10 Nanostructures of Common Metals

	<i>Melinda Mohl, Krisztián Kordás</i>	389
10.1	Post-Transition Metals	390
10.2	Transition Metals	392
10.3	Concluding Remarks	398
	References	399

11 Alloys on the Nanoscale

	<i>Giovanni Barcaro, Alfredo Caro, Alessandro Fortunelli</i>	409
11.1	Concepts and Principles	411
11.2	Preparation and Synthesis	413
11.3	Characterization of Nanoparticles and Nanoalloys	417
11.4	Properties	424
11.5	Nanostructured Bulk Alloys	450
11.6	Applications	457
11.7	Concluding Remarks	458
	References	459

12 Magnetic Nanostructures: Synthesis, Properties, and Applications

	<i>Shashwat Shukla, Pratap Kumar Deheri, Raju V. Ramanujan</i>	473
12.1	Background	474
12.2	Atomic Origin of Magnetism	475
12.3	Magnetic Length Scales and Origin of Nanomagnetic Behavior	478
12.4	Magnetic Nanostructures	483
12.5	Conclusions	505
	References	506

Part C NanoCeramics

13 Nanocrystalline Functional Oxide Materials

<i>Rakesh Shukla, Dimple P. Dutta, Jayshree Ramkumar, Balaji P. Mandal, Avesh K. Tyagi</i>	517
13.1 Synthesis Methods	518
13.2 Optical Properties of Oxide Nanomaterials	524
13.3 Sorbent Properties of Oxide Nanomaterials	532
13.4 Catalytic Properties of Oxide Nanomaterials	536
13.5 Oxide Nanomaterials in Ionics	538
13.6 Conclusions	541
References	542

14 Piezoelectric Nanoceramics

<i>Xiaohui Wang, Shaopeng Zhang, Longtu Li</i>	553
14.1 Introduction to BSPT	554
14.2 Synthesis of BSPT Nanopowders via Sol–Gel Method	555
14.3 Sintering of BSPT Nanoceramics	556
14.4 Grain Size Effect on the Properties of BSPT Ceramics	563
14.5 Summary	567
References	568

15 Graphite Oxide

<i>Wei Gao</i>	571
15.1 Synthesis of Graphite Oxide	572
15.2 Characterization, Chemical Structure and Properties	576
15.3 Applications	589
15.4 Concluding Remarks	592
References	592

16 Compound Crystals

<i>Roi Levi, Maya Bar-Sadan, Reshef Tenne</i>	605
16.1 Nanostructures	605
16.2 Synthetic Methods	608
16.3 Physical Properties	618
16.4 Applications	628
16.5 Conclusions	630
References	631

17 Growth of Nanomaterials by Screw Dislocation

<i>Fei Meng, Stephen A. Morin, Song Jin</i>	639
17.1 Classical Crystal Growth Theories	640
17.2 Theories for Screw–Dislocation–Driven Growth of Nanomaterials	642
17.3 Structural Characterization of these Nanomaterials	645
17.4 Generality of Dislocation–Driven Nanomaterial Growth	649
17.5 Rational Growth of Dislocation–Driven Nanomaterials – General Strategies	658

17.6 Applications	659
17.7 Summary and Perspectives	660
References	661

18 Glasses on the Nanoscale

<i>Hellmut Eckert, Sidney J.L. Ribeiro, Silvia H. Santagneli, Marcelo Nalin, Gael Poirier, Younès Messaddeq</i>	665
18.1 Studying Medium-Range Order in Glasses and Nanoceramics	666
18.2 Nanoceramics	676
18.3 Perspectives and Concluding Remarks	684
References	685

Part D NanoComposites

19 Carbon in Polymer

<i>Robert J. Young, Libo Deng, Lei Gong, Ian A. Kinloch</i>	695
19.1 Materials Basics	695
19.2 Carbon Nanotube Composites	702
19.3 Graphene Composites	716
19.4 Conclusions	722
References	722

20 Nanoparticle Dispersions

<i>Krisztián Kordás, Jarmo Kukkola, Géza Tóth, Heli Jantunen, Mária Szabó, András Sápi, Ákos Kukovecz, Zoltán Kónya, Jyri-Pekka Mikkola</i>	729
20.1 Stabilization of Nanoparticle Dispersions	730
20.2 Nanoparticle Dispersion in Practice	734
20.3 Dispersions of Carbon Nanomaterials	745
20.4 Drying Dispersions on Surfaces	752
20.5 Concluding Remarks	758
References	758

Part E Nanoporous Materials

21 Nanoporous Metals

<i>Yi Ding, Zhonghua Zhang</i>	779
21.1 Preparation of Nanoporous Metals	779
21.2 Properties of Nanoporous Metals	789
21.3 Applications	808
21.4 Concluding Remarks and Prospects	810
References	811

22 Zeolites

<i>István Pálinkó, Zoltán Kónya, Ákos Kukovecz, Imre Kiricsi</i>	819
22.1 Common Zeolite Frameworks	822

22.2	Zeolite and Zeolite-Related Molecular Sieves	823
22.3	Natural Zeolites: Occurrence and Formation.....	825
22.4	Methods of Identification and Characterization	828
22.5	Synthesis of Zeolitic Materials	830
22.6	Ion Exchange, Sorption, and Diffusion in Microporous Materials	836
22.7	Acid-Base Properties of Zeolites.....	841
22.8	Stability and Modification of Zeolite Structures	843
22.9	Zeolites as Catalysts	846
22.10	Some Special Applications of Zeolites	848
22.11	Conclusions.....	850
	References	850
23	Porous Anodic Aluminum Oxide	
	<i>Qiaoling Xu, Guowen Meng</i>	859
23.1	Background	859
23.2	Preparation of AAO Templates	860
23.3	Nanostructures Constructed in AAO Templates	862
23.4	Conclusions and Outlook.....	879
	References	879
24	Porous Silicon	
	<i>Paolo Bettotti</i>	883
24.1	Basics of Porous Silicon Electrochemistry and Formation Models	884
24.2	Other Etching Methods	886
24.3	Porous Silicon Structural Properties	887
24.4	Light Emission from Porous Silicon	890
24.5	Thermal and Electrical Properties	891
24.6	The Role of the Surface	891
24.7	Applications of Porous Silicon	892
24.8	Conclusions.....	897
	References	898
 Part F Organic and Bionanomaterials		
25	Organic Nanomaterials	
	<i>Huanli Dong, Wenping Hu</i>	905
25.1	Preparation/Synthesis of Organic Nanomaterials	905
25.2	Properties of Organic Nanomaterials	910
25.3	Applications.....	925
25.4	Concluding Remarks	930
	References	932
26	Nanocomposites as Bone Implant Material	
	<i>Vinod Kumar, Bipul Tripathi, Anchal Srivastava, Preeti S. Saxena</i>	941
26.1	The Quest for a Suitable Bone Implant.....	942
26.2	Bone	942

26.3	Existing/Conventional Bone Implant Materials and Their Shortcomings	944
26.4	Major Challenges with Existing/Conventional Implant Materials	949
26.5	Nanotechnology and Tissue Engineering	949
26.6	Future Perspectives	965
	References	965

27 Nanofiber Biomaterials

	<i>Rachelle N. Palchesko, Yan Sun, Ling Zhang, John M. Szymanski, Quentin Jallerat, Adam W. Feinberg</i>	977
27.1	Methods of Production	980
27.2	Properties of Nanofiber Biomaterials	986
27.3	Characterization of Nanofiber Biomaterials	993
27.4	Applications	999
27.5	Conclusions and Outlook	1005
	References	1006

Part G Applications and Impact

28 Nanostructured Materials for Energy-Related Applications

	<i>Arava L.M. Reddy, Sundara Ramaprabhu</i>	1013
28.1	Energy-Related Carbon Nanotubes	1013
28.2	CNTs as Support Material for Electrocatalysts in PEMFC	1016
28.3	CNTs as Supercapacitor Electrode Materials	1023
	References	1032

29 Nanomaterials in Civil Engineering

	<i>Jaesang Lee, Seunghak Lee, Eunhyea Chung, Vincent C. Reyes, Shaily Mahendra</i>	1039
29.1	Applications of MNMs in Construction	1041
29.2	Environmental Release of MNMs Used in Construction	1047
29.3	Potential Adverse Biological Impacts and Toxicity Mechanisms	1049
29.4	Mitigation of Environmental and Health Impacts	1052
29.5	Conclusions	1054
	References	1055

30 Plasmonic Nanomaterials for Nanomedicine

About the Authors 1145

Detailed Contents 1163

Subject Index 1181

List of Abbreviations

α -SMA	α -smooth muscle actin	ARPES	angle-resolved photoemission spectroscopy
<i>p</i> -NP	<i>p</i> -nitrophenol	ASTM	American Society for Testing and Materials
0-D	zero-dimensional	ATQD	<i>N</i> -(4-aminophenyl)- <i>N'</i> -(4'-(3-triethoxysilyl-propyl-ureido)phenyl-1,4-quinonenediimine)
1-D	one-dimensional	ATP	adenosine-5'-triphosphate
2-D	two-dimensional	ATRP	atom-transfer radical polymerization
2-PAM	2-pyridine-aldoxime methiodide	AWWA	American Water Works Association
2Q	double-quantum		
3-D	three-dimensional		
3Q	triple-quantum		
4Hop	4-hexadecyloxyphenyl		

A

AA	ascorbic acid
AAM	anodized aluminum membrane
AAO	anodic aluminum oxide
AAO	anodized aluminum oxide
AAS	atomic absorption spectroscopy
Ab	antibody
AC	alternating current
Acac	acetylacetone
ACNT	aligned carbon nanotube
ACQ	aggregation-caused quenching
AChE	acetylcholine esterase
ACP	amorphous calcium phosphate
AD	arc discharge
AEE	aggregation-enhanced emission
AES	Auger electron spectroscopy
AES	3-(2-aminoethylaminopropyl)trimethoxysilane
AFC	alkaline fuel cell
AFC	antiferromagnetically coupled
AFM	atomic force microscopy
AIE	aggregation-induced emission
AIEE	aggregation-induced enhanced emission
ALD	atomic layer deposition
AlPO	aluminophosphate
AM	alveolar macrophage
anti-EGFR	anti-epidermal growth factor receptor
AOC	aromatic organic compounds
APC	antigen-presenting cell
APES	aminopropyltrimethoxysilane
APPES	ambient pressure photoelectron spectroscopy
APS	3-aminopropyltrimethoxysilane
APT	atom probe tomography
APTES	(aminopropyl) triethoxysilane
APTS	3-aminopropyltriethoxysilane
AR	analytical reagent
AR	aspect ratio

B

BASF	Badische Anilin und Soda Fabrik
bcc	body-centered cubic
BCF	Burton–Cabrerá–Frank
BCP	biphasic calcium phosphate
BDAC	benzyltrimethylammoniumchloride
BDNF	brain-derived neurotrophic factor
BEP	Brønsted–Evans–Polanyi relations
BES	Office of Basic Energy Sciences
BET	Brunauer–Emmett–Teller
BF	bright field
BFGF	basic fibroblast growth factor
BG	back-gate
BHJ	bulk heterojunction
bioMEMS	biological microelectromechanical system
BMG	bulk metallic glass
BN	boron nitride
BOM	bubble overlapping mode
BP	buckypaper
BPEA	9,10-bis(phenylethynyl)anthracene
BS	black silicon
BSA	bovine serum albumina
BSI	British Standards Institution
BSP	bis(<i>p</i> -sulfonatophenyl) phenylphosphine dihydrate dipotassium
BT	barium titanate
BT	benzenethiol
BTCP	β -tricalcium phosphate

C

C ₁₆ TAB	hexadecyl trimethyl ammonium bromide
C-PANI	conductive camphorsulfonic acid-doped emeraldine PANI
C3DT	1,3-Propanedithiol
CA	contact angle
CALPHAD	calculation of phase diagrams
CAM	cluster aggregation mode

CBED	convergent-beam electron diffraction	DAPI	4',6-diamidino-2-phenylindole
CBEV	coordination-dependent bond-energy variation	DAPRAL	copolymer of maleic anhydride and α -olefin
CCDB	Cambridge crystallographic data base	DBR	distributed Bragg mirror
CCG	chemically converted graphene	DC	dendritic cell
CCT	correlated color temperature	DC	direct current
CCVD	catalytic chemical vapor deposition	DCE	1,2-dichloroethane
CD	cyclodextrin	DD-PTCDI	<i>N,N'</i> -di(dodecyl)-perylene-3,4,9,10-tetracarboxylic diimide
CFR	continuous flow reactor	DDA	discrete dipole approximation
CHP	cyclohexylpyrrolidone	DDAB	didecyltrimethylammonium bromide
CHT	chymotrypsin	DDC	<i>N,N'</i> -dicyclohexylcarbodiimide
CIE	International Commission on Illumination	DEFC	direct ethanol fuel cell
CIP	current in the plane	DEG	diethylene glycol
CMG	chemically modified graphene	DF	defluoridation capacity
CMOS	complementary metal–oxide–semiconductor	DF	density function
CMP	chemical–mechanical planarization	DFAC	direct formic acid fuel cell
CNF	carbon nanofiber	DFT	density functional theory
CNM	carbon nanotube membrane	DFTB	density functional tight binding
CNT	carbon nanotube	DGU	density-gradient ultracentrifugation
CN-TFMBE	1-cyano-trans-1,2-bis(3',5'-bis-trifluoro-methyl-biphenyl)ethylene	DI	deionized
CO	cuboctahedron	DIC	differential interference contrast
COD	1,5-cyclooctadiene	DLC	diamond-like carbon
COLI	collagen I	DLS	dynamic light scattering
COLIV	collagen IV	DLVO	Derjaguin–Landau–Verwey–Overbeek
COST	Cooperation in Science and Technology	DMA	dimethylamide
COSY	correlation spectroscopy	DMEU	1,3-dimethyl-2-imidazolidinone
COT	1,3,5-cyclooctatriene	DMF	dimethylformamide
cp	close packed	DMFC	direct methanol fuel cell
CP	coherent phonon	DMPO	5,5-dimethyl-pyrroline <i>N</i> -oxide
CP	cross polarization	DMSA	dimercaptosuccinic acid
CPP	conduction perpendicular to plane	DMSO	dimethyl sulfoxide
CPP	current perpendicular to the plane	DNA	deoxyribonucleic acid
CPS	collected photo signal	DND	detonation nanodiamond
CS	cross section	DOS	density of states
CS-PCL	chitosan-graft-PCL	DOX	doxorubicin
CSA	chemical shift anisotropy	dpa	displacements per atom
CSP	colloidal silver preparation	DPSTE	1,2-dipalmitoyl- <i>sn</i> -glycero-3-phospho-thioethanol
CT	charge transfer	DQ	double quantum
CTA ⁺	cetyl-triamine cation	DR	draw ratio
CTA	cetyltrimethylammonium	DRG	dorsal root ganglion
CTAB	cetyltrimethylammonium bromide	DRIFT	diffuse reflectance infrared Fourier-transform
CV	crystal violet	DSC	differential scanning calorimetry
CV	cyclic voltammetry	DT	decanethiol
CVD	chemical vapor deposition	DTAB	dodecyltrimethylammonium bromide
CW	continuous-wave	DTE	desaminotyrosyl-tyrosine ethyl ester
CuPC	copper phthalocyanine	DWCNT	double-walled carbon nanotube
CuTCNQ	copper tetracyanoquinodimethane	DWNT	double-walled nanotubes
		Dox	doxorubicin

D

D4R	double four ring
DAAQ	1,5-diaminoanthraquinone
DAFC	direct alcohol fuel cell

E

ECD	electrochemical deposition
ECDL	electrochemical double layer

ECELL	environmental cell
ECM	extracellular matrix
ECP	electronically conducting polymer
ECSA	electrochemically active surface area
ED	electrodialysis
ED	electron diffraction
EDAX	energy dispersive analysis
EDC	1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide
EDL	electrical double layer
EDLC	electric double-layer capacitor
EDS	energy-dispersive x-ray spectroscopy
EDTA	ethylenediaminetetraacetic acid
EDX	energy-dispersive x-ray spectroscopy
EELS	electron energy-loss spectroscopy
EFM	electrostatic force microscopy
EG	evaporated gold
EIS	electrochemical impedance spectroscopy
EL	electroluminescence
ELISA	enzyme-linked immuno sorbent assay
EM	electromagnetic
EMI	electromagnetic interference
EOF	electroosmotic flow
EPA	Environmental Protection Agency
EPR	electron paramagnetic resonance
EPS	extracellular polymeric substance
EQE	external quantum efficiency
ESC	embryonic stem cell
ESR	electron spin resonance
ESR	equivalent series resistance
ETEM	environmental TEM
EXAFS	extended x-ray absorption fine structure
ElAP(S)O	element aluminophosphosilicate
EPITH	epithelial cells

F

f-SWCNT	functionalized SWCNT
FABMS	fast atom bombardment mass spectroscopy
FBI	Federal Bureau of Investigation
FBR	fluidized bed reactor
fcc	face-centered cubic
ftc	face-centered tetragonal
FDA	Food and Drug Administration
FEB	ferrocene/ethanol/benzylamine
FES	fluctuation-enhanced sensing
FESEM	field emission scanning electron microscope
FET	field-effect transistor
FF	fill factor
FFT	fast Fourier transform
FGO	functionalized GO
FIB	fibrinogen
FIB	focused ion beam

FIPOS	full isolation by porous oxidized silicon
FIT	fluctuation-induced tunneling
FITC	fluorescein isothiocyanate
FLG	few-layer graphene
FMR	ferromagnetic resonance
FN	fibronectin
FND	fluorescent carboxylated HPHT ND
FND	fluorescently enhanced ND
fpRFDR	finite-pulse radio frequency-driven recoupling

G

GMR	giant magnetoresistance
GN	gold nanoparticle
GNC	gold nanoparticle cluster
GNP	gold nanoparticle
GNP	graphite nanoplatelet
GNR	gold nanorod
GNR	graphene nanoribbon
GO	graphene oxide
GOX	glucose oxidase
GSH	glutathione
GTBMD	generalized tight-binding molecular dynamics

H

HA	humic acid
HAADF	high-angle annular dark field
HATU	2-(7-aza-1 <i>H</i> -benzotriazole-1-yl)-1,1,3,3,-tetramethyluronium hexafluorophosphate
HAZ	heat-affected zone
HC	hexagonal channel
HCCN	highly curved carbon nanostructure
HCI	highly charged ion
hcp	hexagonal close packed
HDA	hexadecylamine
HDD	1,2-hexadecanediol
HDDR	hydrogenation–decomposition–desorption–recombination
HDS	hydrodesulfurization
HDT	hexadecanethiol
HEPES	4-(2-hydroxyethyl)-1-piperazineethane-sulfonic acid
HEV	hybrid electric vehicle
HF	hydrofluoric acid
HG	hydrazinium graphene
HIV	human immunodeficiency virus
HL60	human promyelocytic leukemia
HMDA	hexamethylenediamine
HMO	hydrous manganese dioxide
HMOG	heavy metal oxide glass
HMTA	hexamethylenetetramine
HNS	hot neutron source

HOMO	highest occupied molecular orbital	ISO	International Standards Organization
HOPG	highly oriented pyrolytic graphite	ITO	indium tin oxide
HP	Hall–Petch	IZA	International Zeolite Association
HPA	hexylphosphonic acid		
HPC-Py	pyrene-labeled hydroxypropyl cellulose	K	
HPHT	high-pressure high-temperature		
HPMC	Hydroxypropylmethyl cellulose	KE	Kirkendall effect
HPSMAP	poly(styrene-co-maleic anhydride) carrying pyrene	KK	Kramers–Kronig
HSMA	hydrolyzed poly(styrene-co-maleic) anhydride	L	
h-PSMA	hydrolyzed-poly(styrene- <i>alt</i> -maleic anhydride)	LA	longitudinal acoustic
HREM	high-resolution electron microscopy	LAM	laminin
HRN	helical rosette nanotube	LB	Langmuir–Blodgett technique
HRP	horseradish peroxidase	LB94	van Leeuwen–Baerends
HRSEM	high-resolution scanning electron microscope	LBL	layer-by-layer
HRTEM	high-resolution transmission electron microscopy	LCD	liquid-crystal display
HSA	human serum albumin	LDA	local density approximation
hSKMC	human skeletal muscle cell	LDOS	local density of states
HTT	heat treatment temperature	LED	light-emitting diode
HWHM	half-width at half-maximum	LEED	low energy electron diffraction
HiPCO	high-pressure carbon monoxide	LIB	lithium-ion battery
I		LMP	Larson–Miller plot
		LN	less noble
IANH	International Alliance for NanoEHS (environment, health, safety)	LPM	large-pore mordenite
IC	integrated circuit	LPS	lipopolysaccharide
ICP	inductively coupled plasma	LSC	limbal stem cells
ICP-MS	inductively coupled plasma mass spectrometry	LSP	longitudinal surface plasmon
IE	immersion–electrodeposition	LSPR	localized surface plasmon resonance
IF	immunofluorescence	LTA	Linde type A
IF	inorganic fullerene-like nanoparticle	LUMO	lowest unoccupied molecular orbital
iFF	isotactic polypropylene	LYM	lymphocytes
IFSS	interfacial shear strength	M	
Ig	immunoglobulin	M	metalloid
IgG	immunoglobulin G	MA	mechanical alloying
Ih	icosahedron	MAE	magnetic anisotropy energy
IKVAV	laminin derived self-assembling peptide	MALDI-TOF	matrix-assisted laser desorption/ ionization-time of flight
IKVAV-PA	IKVAV polyacrylamide	MAPO	metalaluminophosphate
IL	interleukin	MAPSO	metalaluminophosphosilicates
IL	ionic liquid	MAS	magic angle spinning
IMR	intramolecular rotation	MBE	molecular beam epitaxy
INCO	International Nickel Company	MC	metal cluster
INT	inorganic nanotube	MCFC	molten carbonate fuel cell
IP	iminopyrrole	MCL	maximum contamination limit
IPCE	incident photon to charge carrier efficiency	MCS	ethylene glycol monomethyl ether
iPSC	induced pluripotent stem cell	MD	molecular dynamics
IR	infrared	MDA	malondialdehyde
ipr	isolated pentagon rule	MDA	mercaptopdecanoic acid
		MEA	membrane electrode assembly
		MEMS	microelectromechanical system
		MF	mesoflower
		MF	microfiltration

MFC	microbial fuel cell	NGF	nerve growth factor
MFI	melt-flow index	NHAP	nanohydroxyapatite
MFM	magnetic force microscopy	nHAp	nanohydroxyapatite particle
MGM	metal-graphite multilayer	n-HApC	nanohydroxyapatite/chitosan
MHAP	micron particulate hydroxyapatite	NHS	<i>N</i> -hydroxysuccinimidyl ester
ML	monolayer	NIOSH	National Institute for Occupational Safety and Health

Science and Engineering of Nanomaterials

Robert Vajtai

Nanomaterials possess different properties compared with macroscopic (bulk) materials built up from the same atoms or compounds. The production routes, characterization, and applications of materials sized on the nanometer scale also differ from the bulk.

In this chapter we define nanomaterials and the specific science that describes them, and collect examples of synthesis and applications of a range of these materials; we also dedicate an extended part of the chapter to material properties, e.g., morphology, mechanical, electrical, magnetic, and optical properties. In both the general and specific parts of the chapter, emphasis is placed on the differences from the bulk phase of the same material and, if possible, the size dependence of the various material properties.

Following the handbook format, the chapter is concise and covers various common properties of nanomaterials and correlations with which nanoscientists work; however, we insert specific parts which have some curiosity value, as well as several aspects of our own research.

The techniques, recipes, and later science of making and testing tools, artistic objects, and weapons are the main criteria for the characterization and classification of human historical ages – from the Stone Age through the Bronze and Iron Ages to the Silicon Age we are living in. During the history of mankind, the role of nanomaterials has continuously increased, and the growth of this field is accelerating.

In any modern scientific approach, one should design and synthesize materials with a high level of control. The ultimate material design is when one can plan the structure of the produced materials atom by atom, with every defect, bond length, etc. (for example, 60 carbon atoms, or 72, 80, or even a few million, and 80 boron

atoms built into a cage similar to carbon fullerene), and synthesis should follow precisely this design.

In this chapter, we collect two sorts of information about nanomaterials. To a lesser extent, the common properties of nanomaterials that are discussed in the following chapters are described, whereas in the main part of the chapter, the features and properties of various groups of materials are discussed. This introductory chapter is more exemplary than universal, and in most cases not detailed. More detailed description of the properties and materials discussed here can be found in the later chapters. For navigation in the handbook please use the extended version of the table of contents and the well-detailed subject index.

1.1 History and Definition of Nanomaterials

In this part of the chapter, we briefly mention several important and interesting events from both ancient and modern ages for nanomaterials production and application. We also present how our fellow scientists and government organizations describe and define nanomaterials.

1.1.1 History of Nanomaterials

Although we indubitably live not only in the Silicon but also in the beginning of the Nano Age, almost every chapter in this book, as well as most of the comprehensive review papers in the literature, include historical aspects. Usage of nanomaterials remounts to traditional Chinese medicine [1.6], and Mayan [1.7] and medieval Italian paints [1.8]. Nanomaterials such as the colorful and magically healing inks made of colloid-sized (nano) gold particles were also used in artistic applications such as the Lycurgus cup [1.9] and for producing both small and large stained-glass windows for castles and cathedrals.

In Fig. 1.1, we have collected several examples of famous nanomaterials in chronological order (Fig. 1.1a–f). The timescale in Fig. 1.1g shows these mentioned examples and some other important materials as well as important events. Figure 1.1a–c shows pre-modern era examples of nanomaterial applications. The Lycurgus cup (Fig. 1.1a) includes gold nanoparticles which make its color green when we look at it in the usual way, in reflected light, but red in transmitted light [1.9]. Similarly, metal nanoparticles were used in the magnificent south rose window of Notre Dame Cathedral (Fig. 1.1b). The specific nanostructure with cementite nanowires and carbon nanotubes of damascene-style steels (Fig. 1.1c) [1.10] invented in the Mediterranean, and similar techniques used in Sweden, are representative examples of the first manmade engineered nanomaterials [1.10]. Of course, ancient and premodern technologies could not control material properties on the basis of knowledge of nanometer-scale properties; however, the recipes and methods for nanomaterial production were successful enough to provoke admiration and sometimes fear in *scientists* of their age. At the same time, even with our modern knowledge, the admiration for these first craftsmen of nanomaterials still holds.

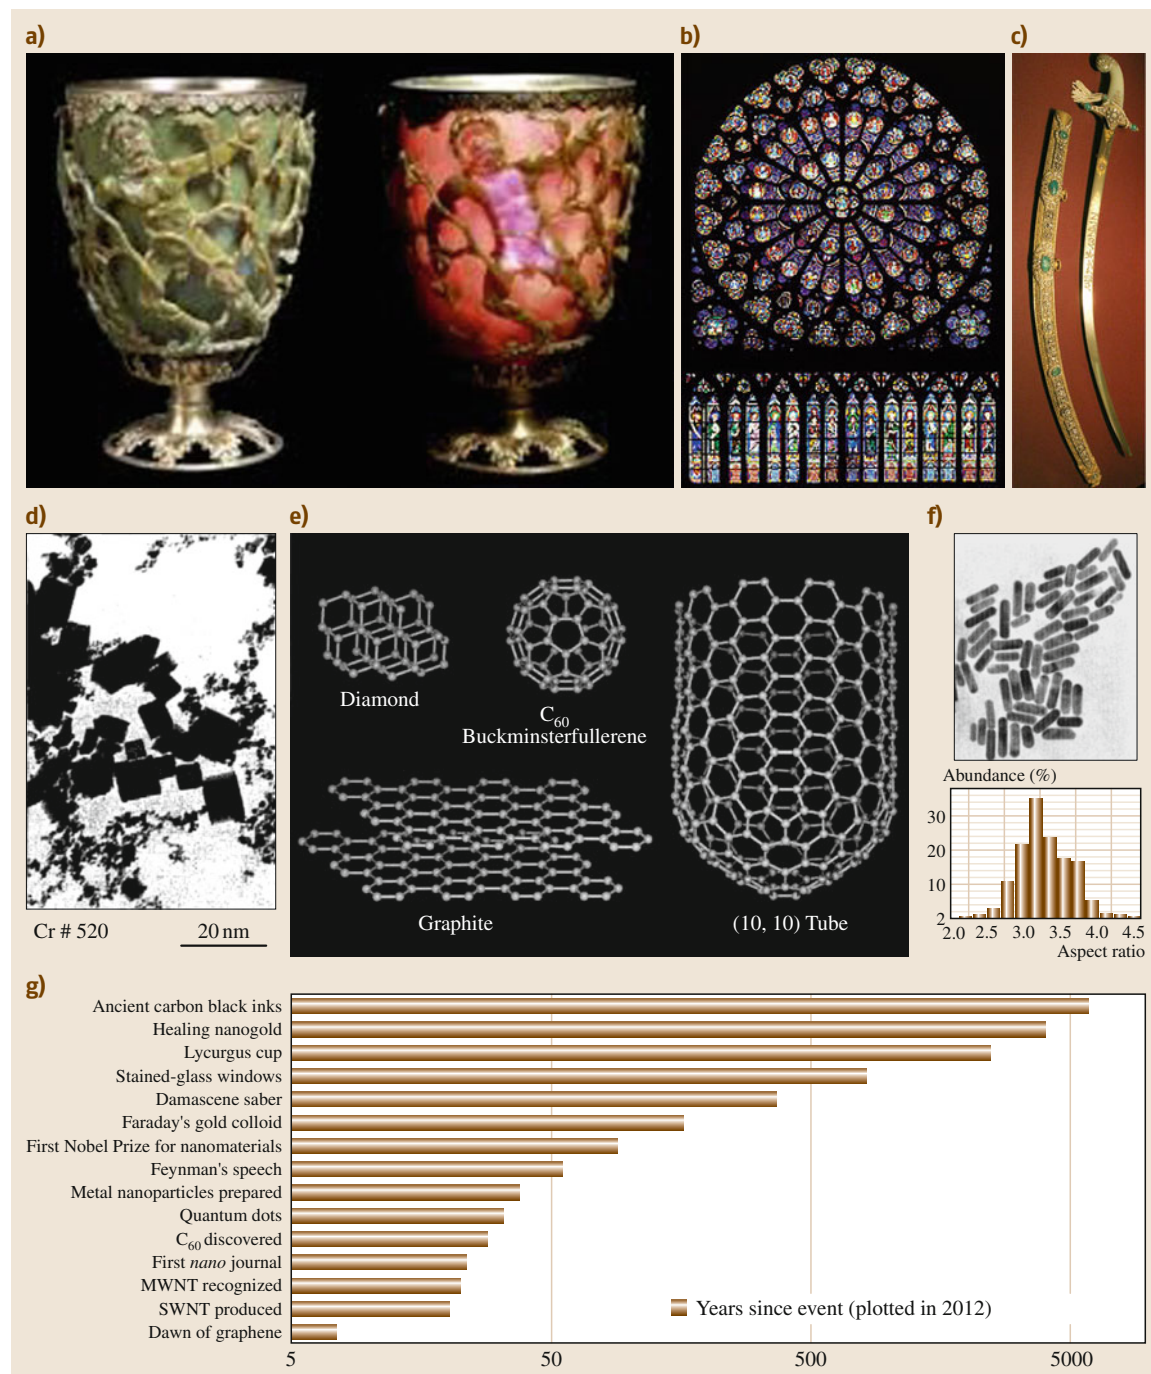

The history of nanomaterials took an interesting turn in the 20th century. First, the discovery of semiconductor-based transistors [1.11] opened the road for

miniaturization and integration of these devices in the first chips [1.12]. In the same decade when the first integrated circuit (IC) was fabricated, Richard Feynman presented his famous lecture [1.13] about the huge information storage capacity of materials if and (as he rather saw it) when one goes to the atomic scale, to store ultimately one bit of information in every atom. He calculated that all of the information stored in the *Encyclopedia Britannica* would fit onto the head of a pin – assuming 120 dpi resolution used in the original print and that the resolution is increased 25 000-fold – without breaking the known rules of physics, and he even envisioned several methods for writing, multiplying, and reading information at that density. In Fig. 1.1d,e, examples of nanomaterials from the last 50 years are displayed. Figure 1.1d shows chromium nanocrystals [1.3] synthesized by the inert gas deposition method [1.3, 14]. Figure 1.1e displays schematics for the newly discovered allotropes of carbon, i. e., nanodiamond, fullerene, nanotubes, and graphene; these materials form such an important part of today's nanomaterial science that at least one chapter in this handbook summarizes knowledge about each of them. Figure 1.1f shows a transmission electron microscopy (TEM) image of gold nanorods and their shape distribution [1.5]; these nanorods are useful in nanomedicine, e.g., for imaging and curing cancer. The bottom part of Fig. 1.1g shows a collection of several historical and novel nanomaterials and related events displayed on a logarithmic scale, dating back from the present to 6000 BC. Even without displaying many important discoveries in the last decades, Nobel and Kavli Prizes awarded for achievements in nanomaterial science, and milestones of commercialization, an obvious exponential acceleration is visible.

Fig. 1.1a–g History of nanomaterial use. (a–c) Premodern examples for nanomaterial applications. (a) The Lycurgus cup photographed in reflective light and in transmission (after [1.1]). The south rose window of Notre Dame Cathedral in Paris, France. (c) Damascus saber (photo Tina Fineberg) (after [1.2]). (d,e) Modern-age milestone examples of nanomaterials. (d) Metal nanoparticles, Cr shown here, produced by the inert gas deposition technique (after [1.3]); (e) allotropes of carbon: nanodiamond, fullerenes, nanotubes, and graphene [1.4]; and (f) gold nanorods [1.5]. (g) Timescale – measured back from today to 6000 BC on a logarithmic scale – of nanomaterial production and events related to nanomaterials ►

In this fast-paced and accelerating scientific and engineering nanoworld, one needs to follow several dozen journals which deal with nanomaterials. In this chapter

and in the whole *Springer Handbook of Nanomaterials*, we try to provide a compass to identify the most important features.

As mentioned earlier, nanomaterials differ from the corresponding bulk materials in many ways, and this dissimilarity is the reason for the formation of a new discipline that describes the properties and behavior of nanomaterials. To exhibit these unique *nanoproperties*,

materials need to have one, most obvious feature: at least one dimension should be on the nanoscale. In this section, we elaborate what nanoscale means and describe the common properties and features that make nanomaterials different from their well-known macroscopic (bulk) counterparts. We also give definitions of nanosize, nanoscale, and nanostructured materials.

Sizes Are Important: Usual Range of Values

First of all we need to define the size range of structures. The term *nano* comes from Greek and means *dwarf*; when used together with units of physical quantities, it expresses 10^{-9} times smaller than the unit. For nanomaterials, the nanoscale mainly means that length (e.g., size, diameter, edge) is measurable on the nanometer scale. Obviously, other physical quantities, such as area, volume, mass, and energy, may be very far from this particular prefix when we use the corresponding SI units. More exactly, most of the definitions place nanomaterials between the approximate limits of 1 and 100 nm. One nanometer is also equal to 10 \AA , using the Angstrom, which is widely used in microscopy and atomic/molecular physics.

In Fig. 1.2, a comparative scale is displayed to show objects with sizes that fall into our common understanding (e.g., ants, pinhead, piece of human hair) to nanomaterials with few-nanometer feature size (e.g., fullerene, nanotube, and DNA (deoxyribonucleic acid)). The figure also shows objects on the intermediate micrometer scale (red blood cells and microelectromechanical systems (MEMS)), and for comparison with another well-known scale, the different ranges of electromagnetic waves. On this scale, nanomaterials can be positioned between the wavelengths of visible/ultraviolet light and x-ray radiation. Being smaller than the shortest visible wavelengths limits the methods available for determining the shapes of nanomaterials by conventional light microscopy.

Different from Bulk

The most important question is *why* materials on this 1–100 nm scale are distinguished and have their own science and engineering. In the size range below 1 nm we can find molecules, atoms, elementary particles, etc., which are different from the bulk but already have their own disciplines. Multiple atoms or molecules behave differently from individual ones for some obvious reasons; e.g., larger size results in different behavior in collisions with atoms. Other changes with increasing number of atoms in the particle include perturbation of the atomic energy levels leading to energy band structures with fine structure; e.g., the energy difference between neighboring states is $E/2N$, where E is the width of the energy band and N is the number of atoms included. The distinction between molecules and nanomaterials, however, is not sharp. C_{60} is considered a molecule and nanomaterial at the same time, and other large molecules are also used as materials in molecular electronics.

At the other end of the size scale, materials start to be different from bulk below 100 nm size, because the effects of quantum confinement on electrical, thermal, and optical properties become significant at about this size.

Another, very important common feature of nanomaterials (e.g., nanoparticles and nanocrystals) is that they have a very high fraction of their atoms on their surfaces. These atoms behave differently from the ones located inside the object or in ideal bulk crystals (in

Fig. 1.3 Schematic of the top-down and bottom-up nanomaterial production procedures

fact, the definition of an ideal crystal includes no physical boundary or surface, as the crystal exhibits infinite periodicity) owing to the asymmetrical forces acting on them; there is a force acting on these atoms which is directed into the particle. The integrated effect of the forces on every surface atom provides a surface tension, the related pressure being so high that it can change bond lengths in crystals. Through this, it also

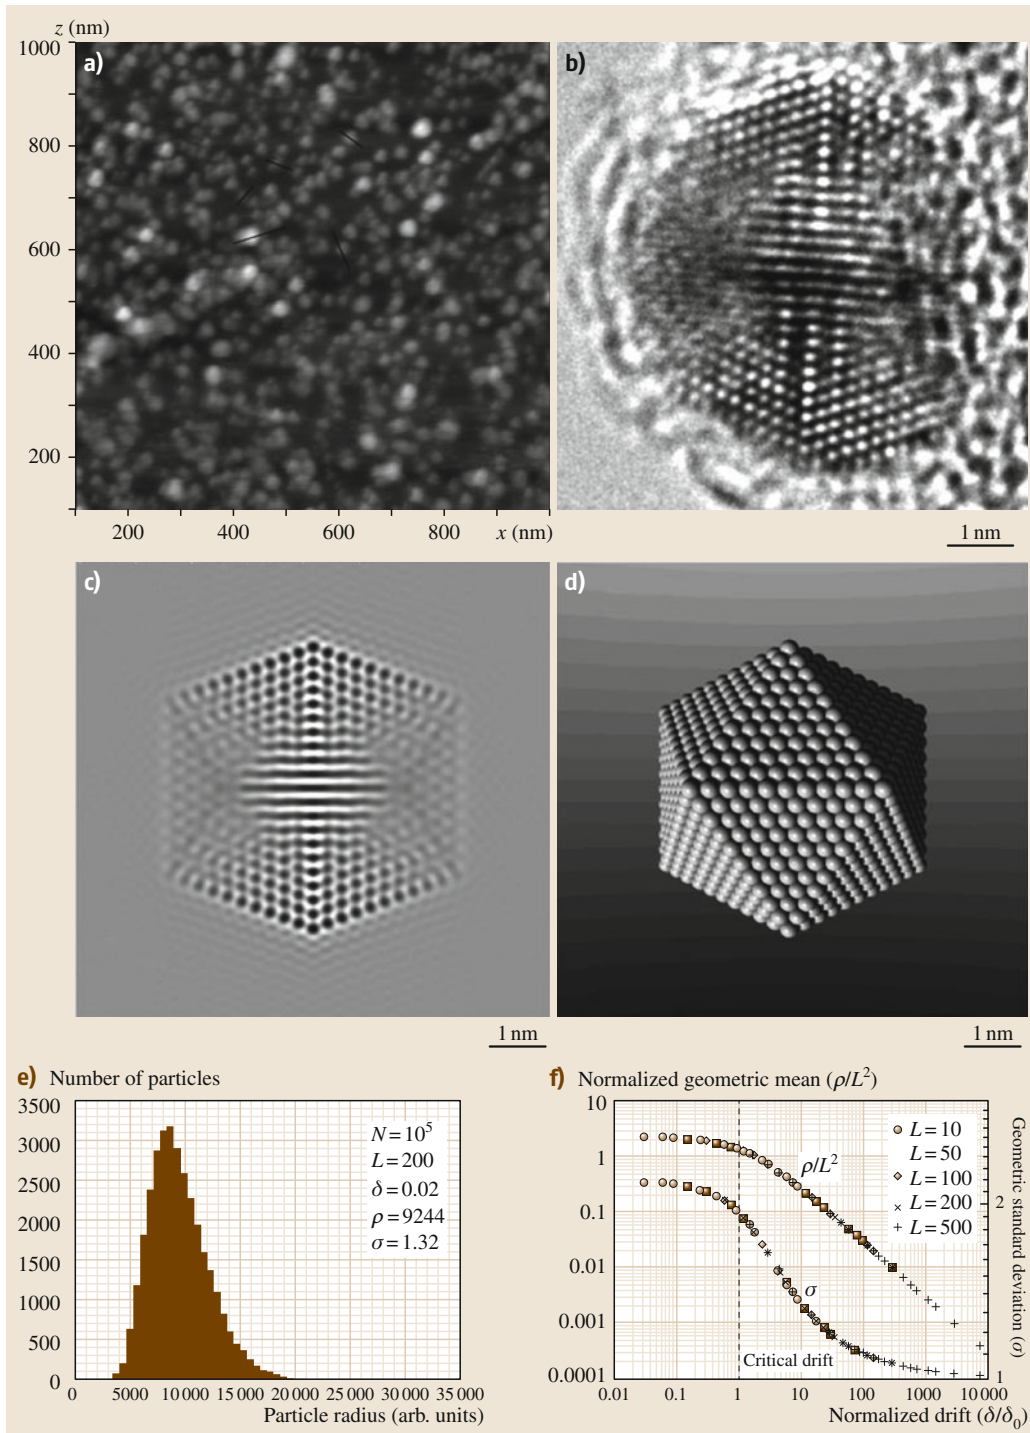

changes mechanical, electrical, and thermal properties; e.g., the melting point of small particles can be considerably lower than the bulk value. In the remainder of this chapter we describe in slightly more detail these changes in the physical properties of nanomaterials as a function of feature size; later chapters in this handbook provide more data for individual material groups.

1.2 Formation of Nanomaterials

Formation of nanosized materials – nanoparticles, nanoporous or nanostructured macroscopic materials – is achieved by two basic routes, namely the so-called top-down and bottom-up methods [1.20, 21]. In the former, macroscopic materials are used to fabricate nanomaterials and nanostructures using – typically – very sophisticated methods. In the latter, nanoparticles and other

nanomaterials are built up from their ultimate building blocks – atoms and molecules – via self-assembly processes. Figure 1.3 shows a comparative representation of top-down and bottom-up methods. In the top-down method we start from bulk materials and fabricate structures or particles on the nanoscale, analogously to the carving of a sculpture (or many small ones) from a mar-

Fig. 1.5a–f Examples for bottom-up assembly of nanoparticles. **(a–d)** Different representations of an AuPd nanoparticle: **(a)** AFM topography of the surface of the sample covered by the nanoparticles; **(b)** high-resolution transmission electron microscopy (HRTEM) image of an individual nanoparticle; **(c)** HRTEM simulation of the same nanoparticle; **(d)** solid-ball atom model of an icosahedral nanoparticle (after [1.18]). **(e,f)** Explanation of the correlation between particle size distribution and the flow properties of the carrier gas. **(e)** Size distribution at medium inert gas drift conditions; **(f)** size and size distribution as a function of drift intensity (after [1.19]) ►

ble boulder; in the bottom-up method we use techniques to build up materials from their component parts, i.e., atoms and molecules, analogously to the building of a cathedral or forming a sculpture from clay.

As procedures used in synthesis and characterization are normally considered parts of nanotechnology rather than nanomaterials science, being discussed in detail in the nanotechnology literature, we only give a very short description for the sake of completeness.

Top-down approaches include evolutionary techniques which are similar to those used in microtechnol-

ogy of integrated circuit fabrication (e.g., photolithography developed to < 20 nm resolution, nanoimprint lithography) along with several completely new methods [e.g., e-beam and focused ion beam (FIB) lithography, direct writing with atomic force microscopy (AFM), and scanning tunneling microscopy (STM)]. Figure 1.4 shows examples of these revolutionary methods. Figure 1.4a presents a demonstration of nanoscale oxidation of silicon in the shape of letters using an AFM tip [1.16], and the same pattern after etching out the oxide by hydrofluoric acid (HF) (Fig. 1.4b). The

printing resolution of the letters corresponds to almost 2 000 000 dpi, which is in the range of Feynman's calculations. Figure 1.4c shows high-aspect-ratio structures fabricated by cryogenic plasma etching of gallium ion-implanted regions of a silicon wafer [1.17]. The authors defined the pattern by FIB lithography and used reactive etching, resulting in structures with 65 and 40 nm diameters and 600 nm height (aspect ratio up to 15).

Bottom-up approaches are quite similar to the formation of macroscopic crystals. However, the thermodynamics of the processes involved for nanomaterials differ from the bulk; as we show later, the free energy, chemical potential, phase diagrams, and kinetics of phase transformations are distinct. Nucleation [1.29] and diffusion are the key elements in the formation of particles; however, other parameters, such as forced or natural drift of the carrier gas in the synthesis (Figs. 1.1 and 1.5) of nanoparticles by the inert gas de-

position method [1.3, 14, 18, 30, 31], also play a very important role in determining the mean particle size and distribution width [1.19, 32]. One of the most widely used bottom-up methods is chemical vapor deposition (CVD), where nanomaterials *grow* on catalyst layers; references to illustrate such materials can be taken from thousands of related papers for single-walled nanotubes (SWNTs) [1.33, 34], multi-walled nanotubes (MWNTs) [1.35], and *h*-BN [1.36] deposition.

Solution-based methods are governed by the concentration of the components used, the temperature of the reaction, and the amount of surfactant; examples include seed-mediated growth of copper nanoparticles [1.37], synthesis of shape-controlled gold nanoparticles [1.38], and specifically the Kirkendall effect applied for preparation of hollow particles [1.39, 40].

Sonothermal synthesis [1.41] and exfoliation of two-dimensional (2-D) materials – for making nanoma-

materials from bulk – are considered bottom-up methods, as we do not have control over the exact manner of formation or properties of each of the particles via macroscopic equipment or tools.

Another possibility is to combine the advantages of the bottom-up and top-down methods. A few such examples are displayed in Figs. 1.6 and 1.7. An interesting way of increasing the resolution of photolithography beyond its physical limitations is by using directed self-assembly and self-orientation of block copolymers [1.42]; structures derived from

this technique are displayed in Fig. 1.6. Figure 1.7a shows schematics of dip-pen lithography; in this case, the AFM manipulation is the top-down component while self-assembly of the printed materials is the bottom-up component. In the widely used method of membrane-based deposition [1.26], we have control over the shape of the alumina template trough parameters such as the etching time, acid type, and temperature; as examples, nanowire, nanojunction nanocup, and nanoring fabrication are collected in Fig. 1.7b–c.

1.3 Properties of Nanomaterials

When nanomaterials are studied, with few exceptions, the goal of the investigation is to reveal the values of physical properties similar to those used to characterize bulk phases of materials. In most cases though, the values of these properties are very different from those in the bulk, depending on the size and morphology of the nanomaterials; this is similar to the way in which the properties of bulk materials also depend on their crystal system (e.g., face-centered cubic (fcc) versus body-centered cubic (bcc)).

1.3.1 Morphology of Nanomaterials

Not only the overall size, but also the shape of nanomaterials is a factor governing other properties; the aspect ratio, porosity, and surface roughness all change the surface-to-volume ratio and thereby other properties. Shape is such an important property that classification of nanomaterials can be based on their dimensionality or aspect ratio. Figure 1.8 shows schematics of nanomaterials limited to zero, one, two, and three dimensions. Zero-dimensional (0-D) objects have nanometer feature size in every direction; one-dimensional (1-D) objects have nanometer size in two directions but larger, e.g., micrometer, length in the third; two-dimensional (2-D) objects are atomically thin sheets of materials, while three-dimensional (3-D) nanomaterials are nanoporous or nanostructured materials. Figure 1.8b, c, and d show examples of 0-D, 1-D, and 2-D materials, respectively. Quantum dots [1.43], nanoparticles [1.3, 14], and fullerenes [1.44] are 0-D objects; the example shown here is a series of TEM images of iron oxide nanoparticles with particle diameters of 6–13 nm, where the diameter was controlled with 1 nm accuracy [1.45, 46]. The one-dimensional material shown

in Fig. 1.8c is a GaAs nanowire mat; the inset shows an individual wire [1.47]. The most famous 1-D materials are the single-walled nanotubes (SWNTs) [1.48, 49] and multi-walled carbon nanotubes (MWCNTs) [1.50]. Two-dimensional materials include graphene [1.51], boron nitride (*h*-BN) [1.36], and graphene oxide [1.52]. In Fig. 1.8d, TEM images of BCN of two and three atomic layer thickness are shown [1.53]. Typical 3-D nanostructured materials are nanoporous metals and ceramics, aerogels, and zeolites [1.54]. Figure 1.8e shows Gleiter schematics of different kinds of 3-D materials [1.55], and Fig. 1.8e,f illustrates the self-assembly of microparticles from azobenzene thiol-functionalized nanoparticles [1.56].

1.3.2 Bonds and Structures

The compressive strain in bulk solid materials is relatively small, even in the case of high applied stress, because the bonds in solids are strong and changing their length requires high pressure and a substantial amount of energy. Quite amazingly, the asymmetry caused by the forces near to surface atoms in solids change the bond length of nanomaterials at least on the scale that we are able to achieve by applying outside forces. The importance of the effect of these changes in bond length increases with the surface atom to volume atom ratio (dispersion) and accordingly on the particle size; it is determinant in clusters and nanoparticles at the lower end of the nanoscale, normally between 1–5 nm (about 50–5000 atoms).

Table 1.1 presents a collection of data for bond length relaxation [1.57], data based on references [1.58–70]. It is clear that bond contraction is between 4% and 30%, and, surprisingly for a bulk material scientist, there is a 30% change in the bond length of diamond,

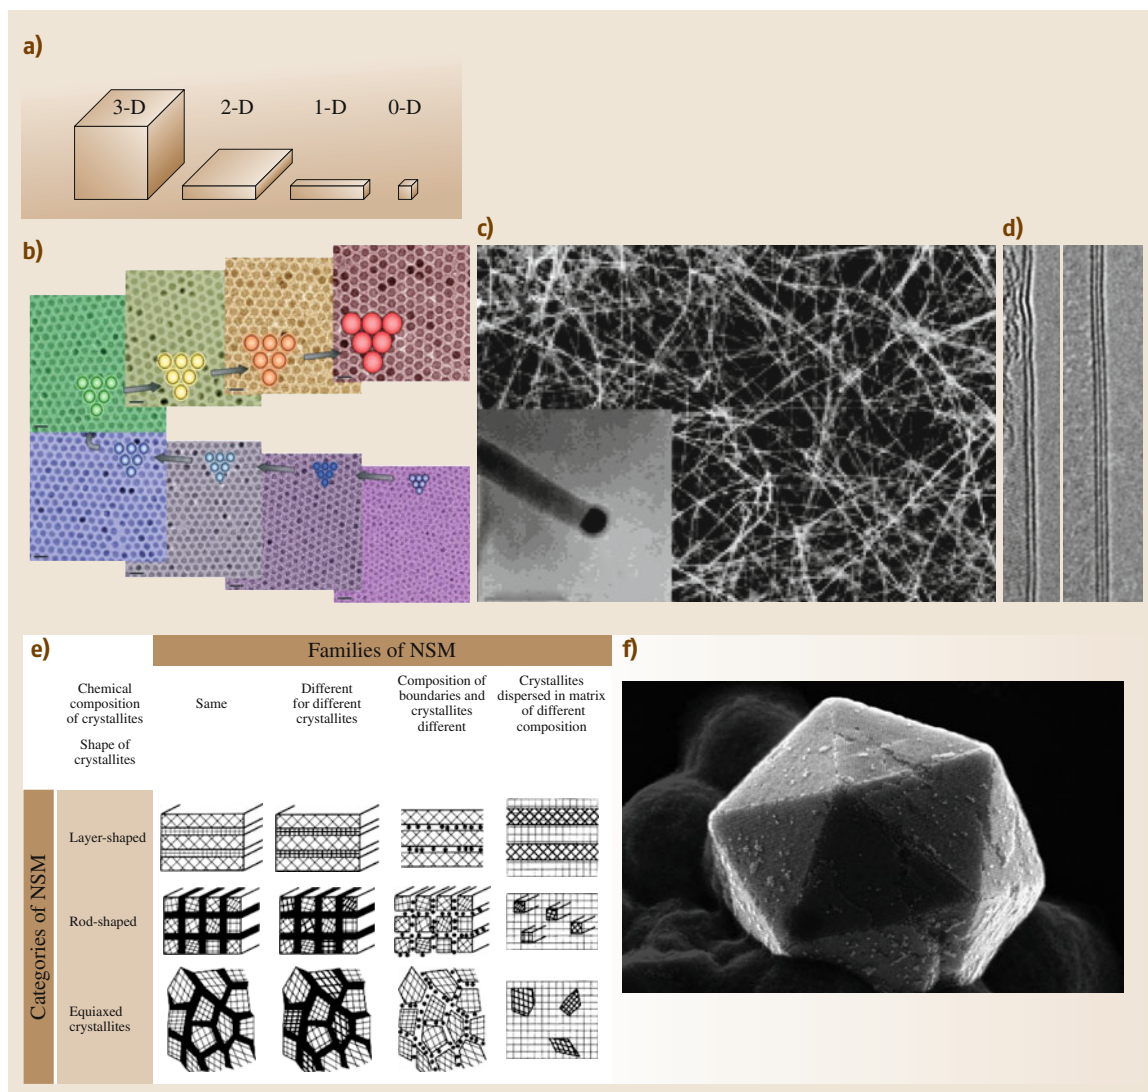

Fig. 1.8a–f Classification of nanomaterials based on their shape, dimensionality, and structure. **(a)** Simple schematics showing 1-D, 2-D, and 3-D nanomaterials. **(b)** 0-D structures: TEM images of iron oxide nanoparticles with particle diameters of 6, 7, 8, 9, 10, 11, 12, and 13 nm (after [1.45, 46]). **(c)** 1-D structures: SEM images of GaAs nanowires with an inset of the TEM image of an individual nanowire (after [1.47]). **(d)** 2-D structures: atomic layers (two and three) of BCN (after [1.53]). **(e)** Schematics of classification of different 3-D (bulk-like) nanostructured materials (NSM) (after [1.55]). **(f)** 3-D structure: a microobject built up from self-organized nanoparticles (after [1.56, 71])

too. The table summarizes data for covalent, metallic, and ionic bonds. While the contraction of ionic bonds is slightly less than that for the other two bond types, it is also obvious that the phenomenon is universal for all kinds of bonds. Table 1.1 also names the changes in the physical properties – energy related to bonds, magnetic

momentum, and hardness – caused by the bond length contraction and reported in the referenced literature.

Figure 1.9 illustrates how the bond length and bond potential depend on nanoparticle size and shape. Figure 1.9a shows the relative change in the lattice constant for several metal nanoparticles – gold, copper, platinum,

Table 1.1 Bond lengths for typical bonds (covalent, metallic, and ionic) and effect on several physical properties (after [1.57], data from [1.58–70])

Bond nature	Medium	$c_1 = d_1/d$	Effect
Covalent	Diamond {111} [1.72]	0.7	Surface energy decrease
Metallic	Ru [1.73] and Co [1.74]	0.9	Atomic magnetic momentum is increased by 25–27% [1.76–78]
	Re [1.75] (1010) surfaces	0.9	
	Fe-W, Fe-Fe [1.79]	0.88	
	Fe(310) [1.77], N(210) [1.78]	0.88	Cohesive energy rises by 0.3 eV/bond [1.81]
	Al(001) [1.80]	0.85–0.9	
	Ni, Cu, Ag, Au, Pt and Pd dimer bond [1.80]	Single-bond energy increases 2–3-fold [1.80]

silver, and aluminum – in the size range of 1–20 nm. Figure 1.9b illustrates how the shape and position of the bond potential change for $\approx 15\%$ lattice contraction. The shorter bond length corresponds to a deeper and narrower potential well, resulting in stronger materials and lower thermal expansion. Figure 1.9c shows nanochain formation for gold, in which chain formation is successful, and for copper, in which chains do not form. The bond energy for atoms in the nanometal chain structures is 2–3 times larger than for bulk materials.

1.3.3 Mechanical Properties of Nanomaterials

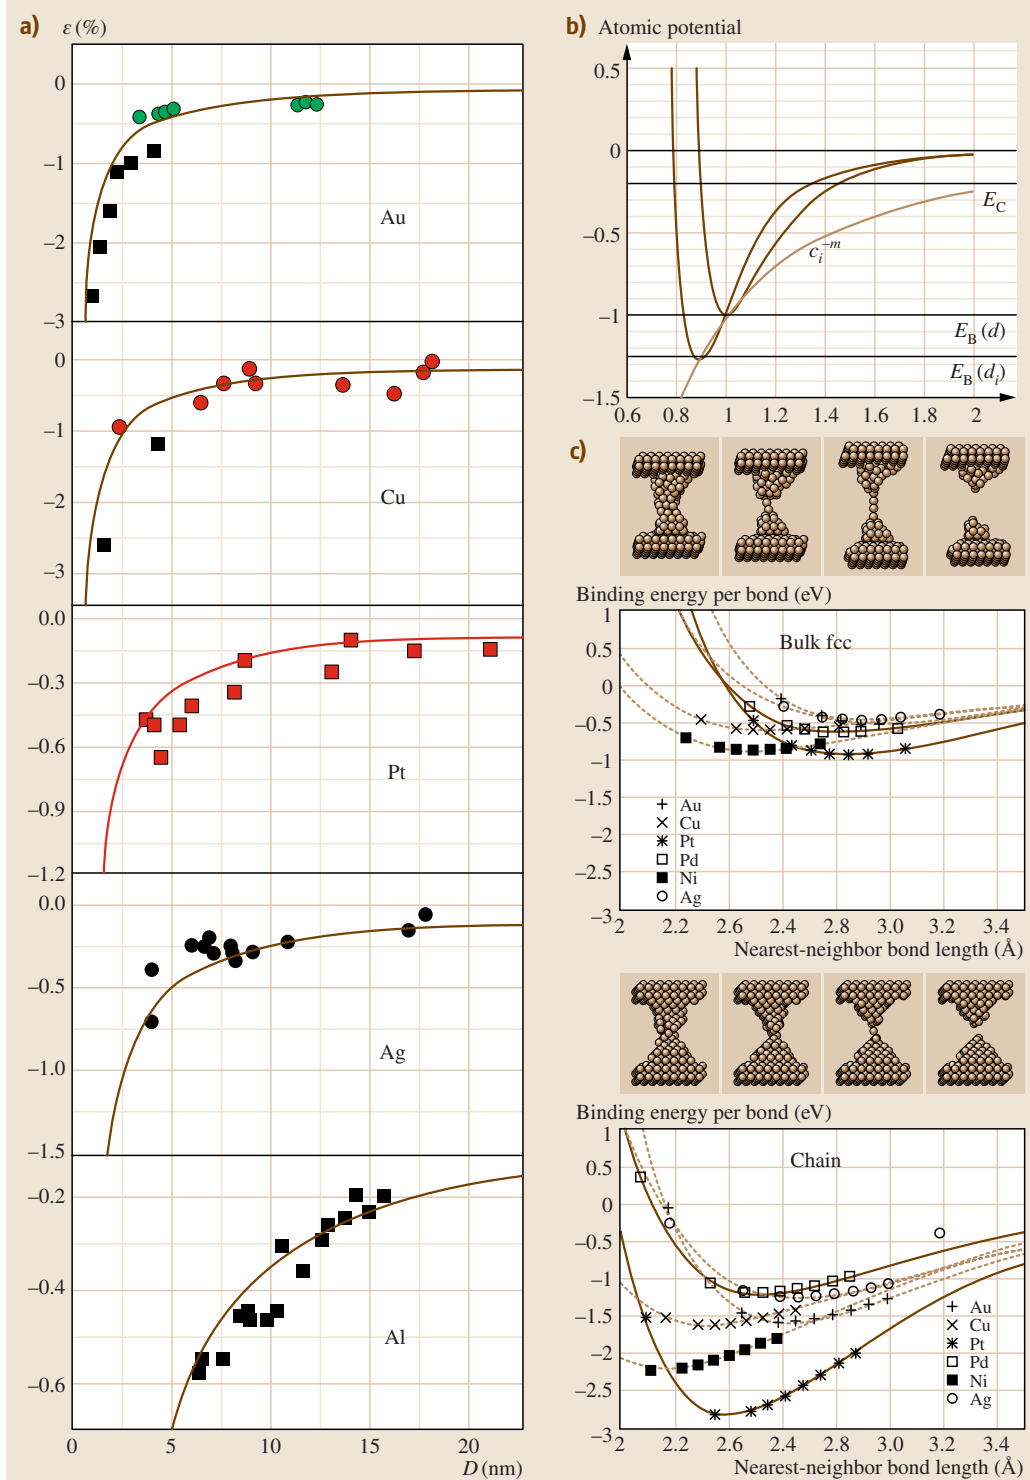

Nanomaterials and nanostructured materials have distinct mechanical properties for several reasons: Firstly, the shorter bond length results in stronger and stiffer materials, as mentioned in the previous section; Furthermore, the limited size of the units of the material diminishes the probability of certain defects; e.g., grain boundaries are very rare in small nanoparticles. It is well known that carbon–carbon bonds in the hexagonal lattice of graphite are the strongest ones in any solid, and second only to the N–O bond overall. On the macroscopic scale, however, we do not consider graphite an extraordinarily strong material as its bonds in the *c*-crystal direction are weak, and the lateral strength in the *a*–*b* plane is diminished greatly by the fact that the layer is not continuous, so pulling forces easily disinte-

grate the crystal. On the nanoscale, the hexagonal sheets of carbon are separated, and strength is measured on individual flakes and domains. The role of point defects in nanomaterials, from the point of view of mechanical strength, is not as critical as for discontinuities in bulk materials. Graphene and carbon nanotubes have high strength and Young’s modulus owing to these strong in-plane bonds.

It has been shown that metals with grain structures have an optimum grain size for minimum creep [1.89]; the optimum grain size for most metals is on the few-nanometer scale, corresponding to the limit of Hall–Petch hardening by grain size reduction. Similarly, in the case of ceramics, the maximum Vickers hardness is measured at the optimum grain size that falls in the range of 10–50 nm [1.90, 91].

Figure 1.10 demonstrates several basic mechanical properties of nanomaterials. Figure 1.10a and b show the particle size dependence of hardness for

Fig. 1.9a–c Typical effects of properties of bonds in nanoparticles as a function of particle size. **(a)** Dependence of the bond length on particle diameter for several metals (after [1.86]). **(b)** Increase of the bond energy density with decreasing particle size and the consequently shorter bond length (after [1.57, 87]). **(c)** Bond strength as a function of dimensionality. Chain formation of gold atoms and failure to achieve the same with copper. Binding energies of bulk and atomic 1-D chain structures (after [1.88]) ►

metals and intermetallic alloys [1.92], respectively. In the case of metals, there is an obvious trend for the hardness to be 3–10 times higher for the smallest nanoparticles than for those larger than 100 nm, latter is the value corresponding to the bulk material. For the alloys, a trend of increasing hardness is visible for the 100 to ≈ 40 nm range; however, in many cases this trend becomes softening for further diminishing nanoparticle sizes. Figure 1.10c,d shows buckling of carbon nanotubes [1.93–95]. While SWNTs have very high Young's modulus and relatively high stiffness against tensile forces [1.96], they can be deformed by compressive forces, which makes them ideal high-resolution yet gentle and forgiving AFM tips [1.95]. Figure 1.10e,f demonstrates the in-plane mechanical strength of a graphene sheet based on nanoindentation carried out by an AFM tip [1.97].

1.3.4 Electrical, Magnetic, and Optical Properties

Nanoscale materials, especially with dimensionality of zero to two, exhibit intriguing electromagnetic behavior, as the most important effects and properties are derived from the quantum confinement of the wave function of the charge enclosed in the particles. In the nanometer-sized dimensions of the material, the wave function has a limited number of solutions. This results in changes in several electrical properties: with the decreasing feature size the bandgap becomes wider, the conductivity decreases and the density of states decreases. Optical properties change accordingly, as the absorbed and emitted photons depend on the energy difference between the states among the bands or in their fine structure. Beyond this, quasiparticles are generated due to the confined space. An electron–hole pair, i.e., an exciton, carries energy in nanomaterials without motion of net charge. Plasmons, surface plasmons (polaritons), and polarons play a key role in nanomaterial interactions with optical phonons, e.g., causing the color dependence of gold colloids as a function of particle size. Magnetic properties are also governed by the size of the nanomaterials; e.g., superparamagnetic materials exist below the size of the domain size.

Electrical Properties

Electrostatic forces play a major role in nanoparticle formation and also have an important effect on nanomaterial properties [1.71]. Most of the larger structures built up from nanomaterials are held together by van der Waals forces. One of the advantages attributed to

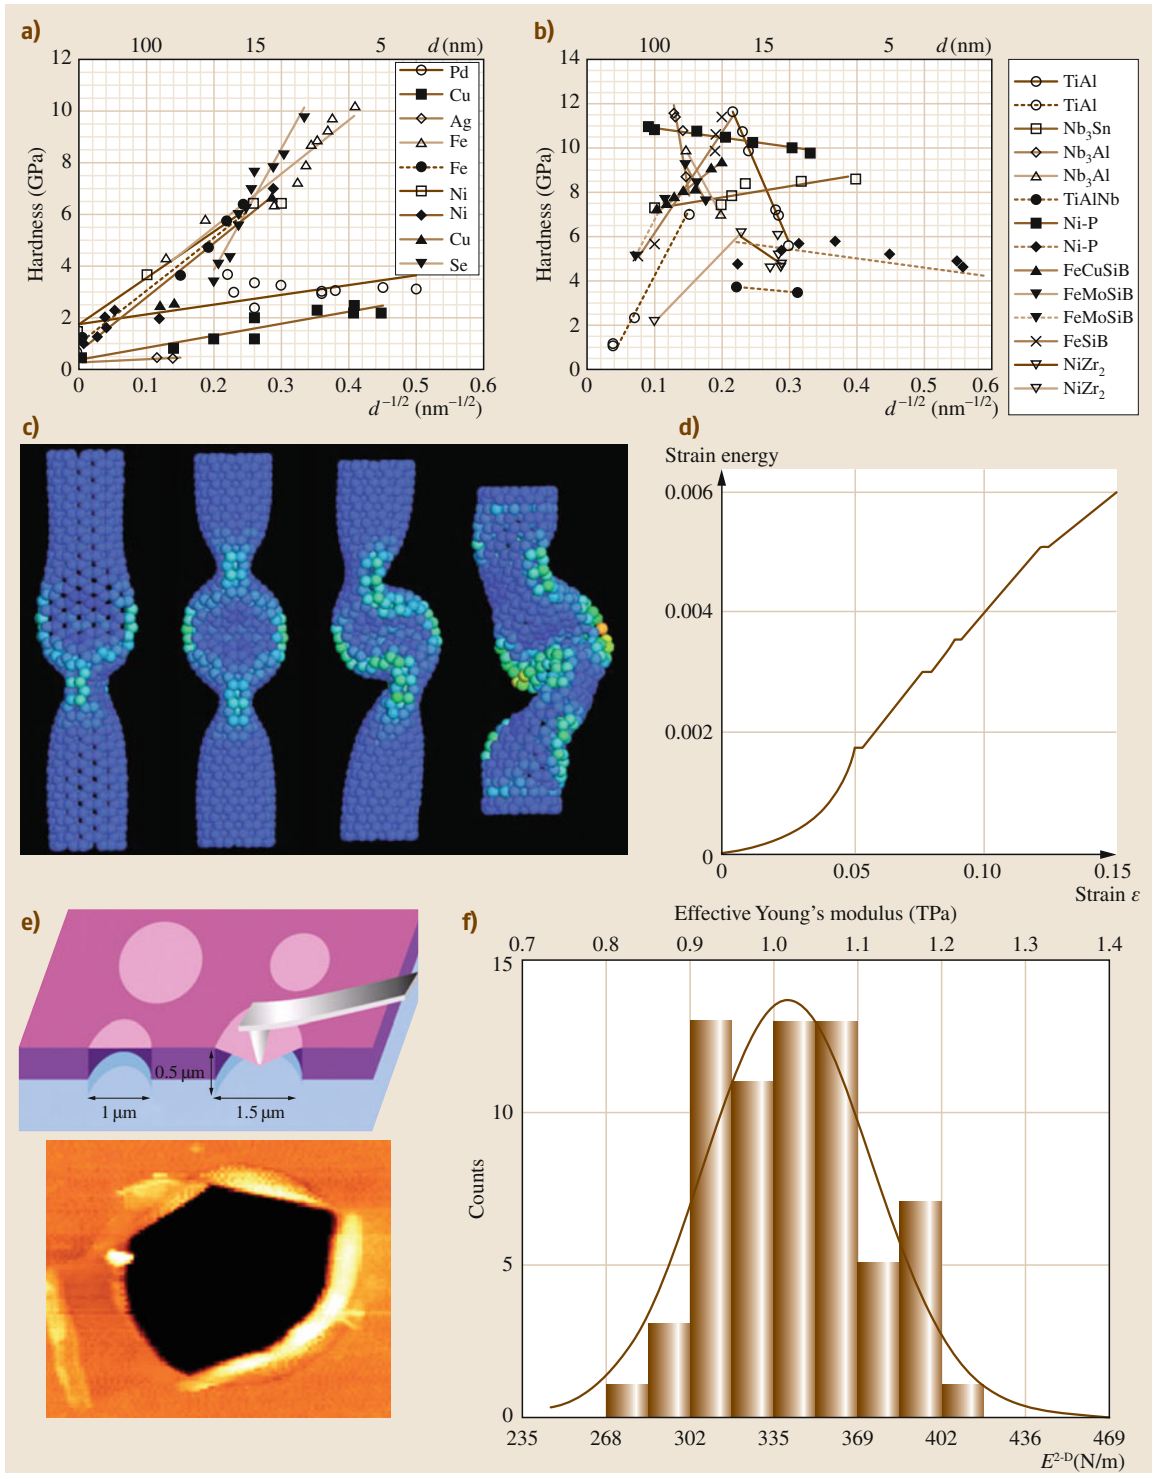

the high aspect ratio of 1-D structures is the field enhancement of the electrostatic potential, which enables a low turn-on voltage for field emission [1.98,99].

Nanomaterials, especially 1-D structures such as nanowires and nanotubes, conduct electrical current differently compared with bulk conductors. The limited size in the direction perpendicular to the axis and the atomically organized structure of the 1-D objects – crystals or nanotubes, e.g., molecules – result in weak phonon–charge carrier interaction and ballistic transport. In the ballistic regime of electrical conduction, the resistance does not depend on the length of the conductor but rather on the number of conductance channels used, following Landauer's law [1.100]. Often, there is a single channel, and the quantum nature of the conductance as a function of the number of channels can be demonstrated, e.g., for carbon nanotubes [1.101]. However, in other reports, e.g., on nanotubes used to build field-effect transistors (FETs), the conductance mechanism is considered to be diffusive [1.102].

Another important effect in devices made of nanosized conductors and semiconductors is the Coulomb blockade that occurs when new charge carriers cannot enter the conduction channel while another charge carrier occupies it, as demonstrated for single-molecule devices [1.103]. This phenomenon enables the functioning of single-electron transistors (SETs) even at room temperature [1.104]. SETs are also useful to investigate spin–spin interactions between localized and mobile electrons, i.e., the Kondo effect, more effectively than in macroscopic systems [1.105].

High current-carrying capacity – i.e., no failure caused by electromigration – of individual carbon nanotubes, both single-walled (4×10^9 A cm²) [1.106] and multi-walled ($> 10^{10}$ A cm² at 250 °C) [1.107], and wires made of nanotubes has also been demonstrated. Since carbon atoms are bound into the nanotube by covalent bonds, the charge carriers and high temperature cannot easily move them away from their original location. The state-of-the-art specific conductivity of carbon nanotube

Fig. 1.10a–d Selected mechanical properties of nanomaterials. **(a,b)** Hardness of metals and intermetallic alloys as a function of grain size in nanophase materials (after [1.92]). **(c),(d)** Molecular dynamics computation of the behavior of a carbon nanotube under compressive force. The structure in the strain energy curve corresponds to the modes of buckling (after [1.93–95]). **(e,f)** Measurement and values of the Young's modulus for a suspended graphene sheet on an alumina template by AFM (after [1.97]) ►

As the voltage was low (100 mV), each nanotube added only one channel to the conductance and the measured values were nG , where n is the number of nanotubes/channels. A larger number of nanotubes resulted in conductance up to 1000 G (after [1.111]). **(d)** Transistor characteristics of a FET device where the active element was a single-layer graphene channel. The figure displays the transconductance, charge carrier mobility, **(e)** and current gain **(f)** as a function of top and bottom gate voltage, carrier density and temperature, frequency and drain voltage, respectively (after [1.112])

fibers surpasses the values for all conventionally applied metallic conductors (Cu, Al, Au, etc.) [1.108].

Figure 1.11 shows a collection of electrical properties. Figure 1.11a shows a schematic of the dependence

of the density of states (DOS) on the dimensionality of the nanomaterials; the larger the number of quantum-confined dimensions, the higher the number of discrete states in the DOS [1.109]. Figure 1.11b shows how the

resistance of a carbon nanotube increases as it loses carbon layers from its wall; the resistance, and accordingly the conductivity, also changes in quanta, illustrating the independence of the conductance channels in each layer [1.110]. Results of a similar experiment are shown in Fig. 1.11c. Here, the conductance of a nanotube bundle was measured when one, two, three, and four nanotubes were included sequentially in a circuit including a contact made of mercury [1.111]. In both cases, the size of the quantized steps of the conductance change – following the Landauer law – is equal to G_0 . By immersing the nanotube bundle further into the mercury electrode, the authors measured conductance as high as $\approx 1000 G_0$. In Fig. 1.11d–f, the characteristics of a FET based on a single-layered graphene sheet are shown [1.112]. First, the structure of the device and the conductance as a function of the top gate (TG) voltage are displayed at different back-gate (BG) voltages. The electron and hole mobility were calculated from Hall-effect measurements, being higher than $5000 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ for low temperatures and carrier densities, and around $3000 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ at room temperature (RT). The high-frequency behavior of the device shows $1/f$ dependence of the current gain as a function of frequency, and the cutoff frequency is in the range of 100 GHz.

Magnetic Properties

The magnetic properties of nanomaterials depend strongly on the characteristic size, i.e., the diameter of nanoparticles or the grain size of nanostructured material, which is normally small in comparison with the magnetic domain size of the material. The configuration of thin films and few-domain nanoparticles was investigated by Kittel [1.113]. Figure 1.12a presents these configurations and the energy density for the various configurations in thin films, showing that (for small size) the single-domain system is energetically favorable. Nanomaterials can be classified according to the type of interaction among the magnetic particles, extending from no interaction in a well-distributed nanoparticle system to strongly interacting nanostructured materials [1.114] (Fig. 1.12b). Ferrofluids consist of particles surrounded by surfactants, capping agents, and solvents, forming an independent system, while alloys with magnetic constituents are strongly correlated.

Superparamagnetic materials behave similarly to paramagnetic materials. However, the magnetization value is considerably higher and the particles keep their magnetization values for a measurable timescale, e.g., several minutes. The magnetization curve of su-

perparamagnetic materials does not show hysteresis, and the exact shape depends on the particle size or its distribution.

By introducing defects into the lattice of carbon, e.g., implanting nitrogen or carbon atoms into nanodiamond, ferromagnetic behavior is observable [1.115]. Also, ferromagnetism is measured on monoatomic cobalt structures at low temperature (10 K), showing the interaction between neighboring atoms [1.116]. During Mackay transformation and Bain transformation, the crystal structure is changing, and the magnetic properties follow the crystal symmetry [1.117], as shown in Fig. 1.12c.

Figure 1.12d shows the grain size dependence of the magnetization of Ni films of different grain sizes, i.e., the magnetization hysteresis loops, the coercive force values, and the relative change in the magnetization [1.118]. In all three cases, the changes are significant below feature size of 10 nm.

Optical Properties

It is a common misbelief that nanomaterials cannot be seen by the naked eye or be detected by optical microscopy. This misbelief is based on the fact that the nanoscale is defined as 1–100 nm while the wavelength of visible light ranges between 400 to 800 nm; however, this scale difference only means that size and shape cannot be resolved by visible-range photons. In fact, there are plenty of interactions between atoms, molecules, and nanomaterials with light, and some of these interactions are applicable to detect the size and morphology of nanomaterials. All of these detection methods need to be first used in parallel with other approaches to measure, e.g., nanoparticle size, and after this *calibration*, the optical method itself can serve as a fast and easy measurement approach. In the case of gold nanoparticles or thin layers of graphene, practiced researchers can tell their size or thickness by eye alone, in the latter case with subnanometer, atomic accuracy. In this section, the main features of the optical properties of nanomaterials are described, while detailed description of these properties for specific nanomaterials is included in the relevant chapters of this handbook.

Optical properties – similarly to the electrical ones – are governed by quantum confinement: the lower dimensionality and smaller size result in a larger energy difference between neighboring discrete energy levels in the DOS, and accordingly higher excitation energy (Fig. 1.13) [1.109]. Inasmuch, the smaller the particle, the shorter the wavelength in the absorption spectrum, and the color shifts from red to blue. This interac-

tion with photons can be interpreted by introducing a quasiparticle known as the surface plasmon (SP) to represent the oscillations in the confined space [1.43]. The absorption spectrum has a maximum when the SP–photon interaction is strongest, at the surface plasmon resonance (SPR) wavelength. The SPR for different nanoparticles depends – beyond the size – also on the material and shape of the nanoparticles. Figure 1.13a demonstrates visible-range colors caused by SPRs of different energy for several basic shapes of gold, silver, and alloy nanoparticles [1.119]. Figure 1.13b shows a particular case from [1.119], where the resonance wavelength shifts when the silver nanoshell particles are coated with a gold layer of increasing thickness. Figure 1.13c presents a silver nanoprism preparation method where the size distribution and accordingly the absorption spectrum are well controlled by the wavelength of light used in the photo-induced reaction. Another interesting phenomenon is the shift in the absorption of gold nanotriangles from 800 nm to 600 nm with the extent of the truncation of the tips [1.120].

Along with other microscopy techniques, the optical property corresponding to Raman scattering [1.121, 122] provides insightful information into the local bonding system of nanomaterials through phonon–photon interactions. It is used for characterizing a wide range of materials from metals to oxides; one of the characteristic examples is its application in studying carbon nanomaterials. Figure 1.13d shows spectra of carbon structures for comparative analysis. Graphene has two characteristic peaks, the ratio of the intensity of the G and G' peaks depends on the number of layers in the 2-D structure. In the case of carbon nanotubes, the D and G peaks dominate the spectra, while for SWNTs, the radial breathing mode (RBM) is also present and provides information about the diameter and (to some extent) the chirality of the nanotubes. Shifts, shoulders, and new peaks in the spectra can be interpreted as signals caused by defects in the bonds or in the structure.

Fluorescence [1.123] and bandgap photoluminescence are also characteristic properties of nanomaterials, the latter being applied, e.g., to study the diameter and chirality of SWNTs in solutions [1.124, 125]. The schematics of the band structure with the first and second van Hove optical transitions and the measured values on a Kataura plot are displayed in Fig. 1.13e.

1.3.5 Thermal Properties

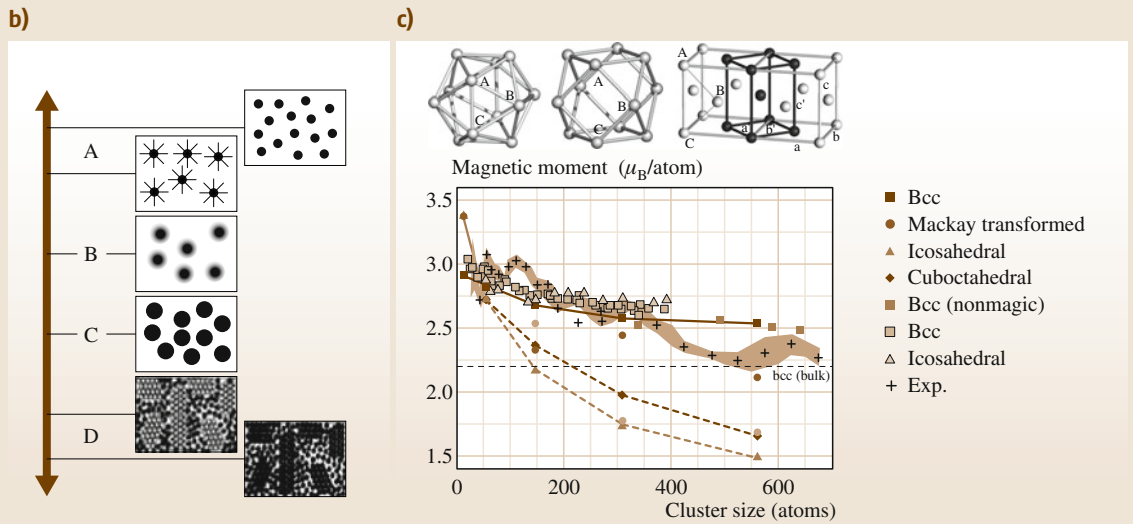

Thermal conductivity, specific heat, melting point, and glass-transition temperature are just a few examples

Fig. 1.12a–d Selected magnetic features in nanomaterials. **(a)** Domain configurations studied by Kittel. For thin films the single-domain configuration has lowest energy for thickness below 300 nm. Several domain configurations for nanoparticles also were suggested in this paper, which was published in 1946 [1.113]. **(b)** Schematics for the main types of nanostructures for magnetic behavior, including independent ultrafine particles (e.g., ferrofluids), core–shell particles with magnetic core, particles as fillers in a matrix, and small crystallites in a noncrystalline matrix (after [1.114]). **(c)** Mackay transformation shows the magnetization changes as a function of crystal structure. Schematics of icosahedron, cuboctahedron, and fcc with inscribed body-centered tetragonal Bain cell and the magnetization as a function of cluster size are displayed (after [1.117]). **(d)** Magnetic hysteresis loops, coercive forces, and relative changes compared with the bulk value for Ni film with different grain sizes is displayed (after [1.118]) ►

of thermal properties that strongly depend on the particle or feature size of nanomaterials. Phase diagrams of nanomaterials depend on the particle size, shape, and even their environment.

The Gibbs–Thomson equation describes the decreasing tendency of melting point with decreasing particle size. For spherical particles, for instance, it predicts that the difference in the melting point has inverse dependence on the diameter of the particle. Figure 1.14a shows the melting point of gold particles as a function of particle size D [1.90, 126]. Below 20 nm the decrease is observable, and for particles smaller than 3 nm the melting temperature decreases by ≈ 600 K. Figure 1.14b illustrates an unusual behavior. In specific cases, indium particles embedded into an aluminum matrix show a melting point increase with decreasing grain size; this exceptional behavior is caused by the interaction with the matrix: here, for smaller grain size, the surface energy of the grain decreases.

Figure 1.14c shows experimental demonstrations of the theoretically predicted, unusually high thermal conductivity [1.127, 128] of carbon nanotubes and graphene, ≈ 6000 W/(m K). Values of thermal conductivity measured on a thick layer of aligned SWNTs range up to 240 W/(m K) in the direction of alignment, and approximately ten times lower in the perpendicular direction. A similar trend was observed for the heat conductivity of aligned carbon nanotube forests [1.129]. For the measurement of thermal conductivity in graphene sheets, the shift in the position of the Raman G peak was investigated. This shift

corresponds to $\approx 5000 \text{ W}/(\text{m K})$ heat conductivity. Another interesting hybrid system is displayed in panel Fig. 1.14d, where covalently bonded carbon nanotube pillars connect parallel graphene sheets to each other. By changing the geometry of this unique system, i.e., the length and separation of the pillars, one can tune for different vertical and lateral thermal conductivities.

1.3.6 Chemical Properties, Reactivity, and Functionalization

Chemical approaches are used in almost all nanomaterial preparation processes. As prepared, nanomaterials have extraordinary properties; however, for many applications they need to be modified, and accordingly further chemical treatment is needed. Some nanomaterials, e.g., fullerenes and nanotubes, can be considered as molecules, and their chemistry is quite well defined. In the case of metallic and ceramic nanomaterials, the reactions and products depend on the size and exact shape of the nanomaterials used. In the narrower definition, we consider only modifications to the strong bonds – covalent, ionic, and metallic – of the materials; in the wider definition, modifications to weak interactions – hydrogen bonding and van der Waals interaction – among parts of the new nanomaterial are also considered. Exchange reactions and chemical transformations of nanoalloys also represent a vast field of nanomaterial chemistry [1.131].

In the scope of this short introduction, a few example reactions are presented, where changes in covalent bonds are dominant. Small pieces of graphene, also called graphene molecules, can be handled by typical methods of organic chemistry; they can be decorated, or connected to each other, and their lateral size can be controllably increased or decreased [1.132]. In Fig. 1.15a, schemes of several graphene molecules are displayed, demonstrating differently sized, bare, and R-functionalized samples. The figure also presents a larger molecule, namely a *nanopropeller*, which is built from three graphene flakes connected to each other. The color of these materials depends on the size of the molecules; with increasing size, the color shifts from blue in the direction of red.

Another example of well-defined molecules which are considered nanomaterials is the fullerenes. These can be modified in two ways: additional atoms are either included inside the cage of the fullerene or added as outside ligands, being called endohedral (inner) and exohedral (outer) fullerenes, respectively. An uncommon example is that of B_{80} [1.133], a fullerene decorated by

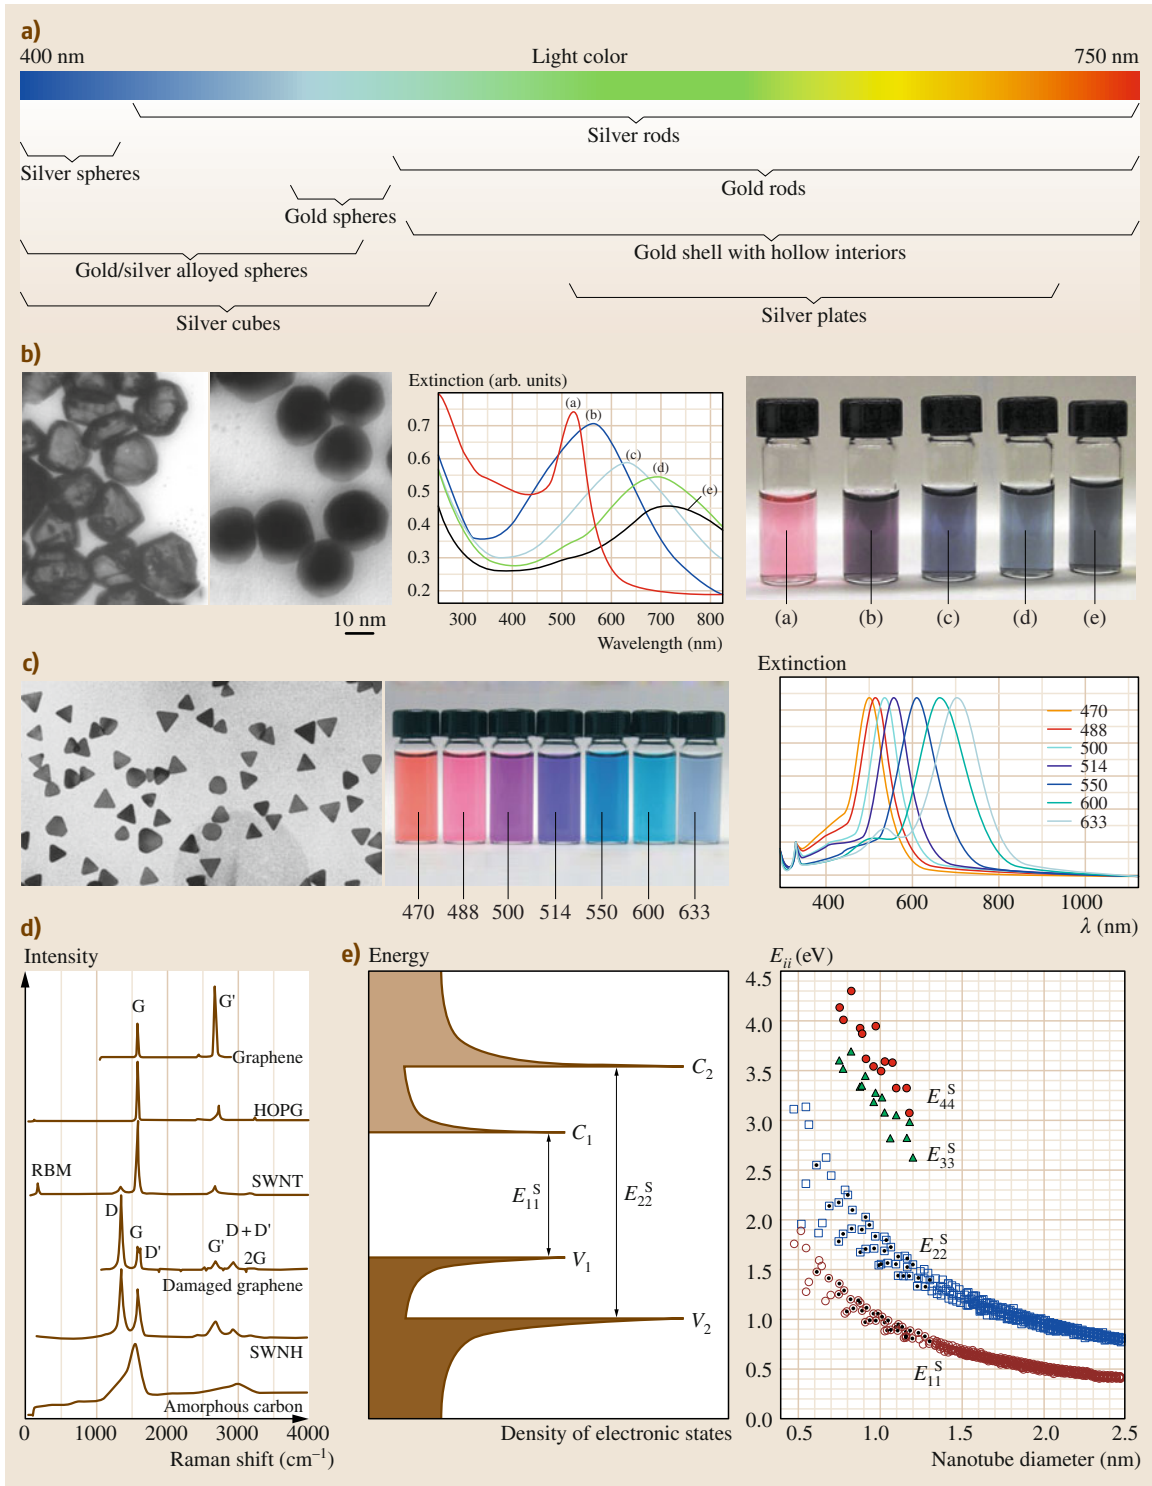

Fig. 1.13a–e Selected optical properties of nanomaterials. **(a)** Typical surface plasmon resonance spectral ranges of silver and gold nanoparticles having various morphologies, compositions, and structures (after [1.119]). **(b)** Ultraviolet-visible (UV-Vis) extinction spectra and photo of solution of silver nanoshells coated with different thicknesses of gold, and solid gold colloids; **TEM** image of the shell and solid particles (after [1.119]). **(c)** **TEM** image of silver nanoprisms and extinction spectra of nanoprisms prepared with illumination by various laser wavelengths (after [1.130]). **(d)** Raman shift measured on different types of graphene-related nanocarbons. The main features (**RBM** and disorder-induced D, D', and D + D' bands; first-order Raman-allowed G band; and second-order Raman overtones G' (2iTO) and 2G) are labeled in some spectra, but the assignment applies to all of them. The analysis of the frequency, line shape, and intensity of these features at different exciting laser wavelengths provides a great deal of information about each respective sp^2 carbon structure (after [1.122]). **(e)** Method for identifying single-walled carbon nanotube diameters by spectrofluorometry (Kataura plots). First and second van Hove optical transitions are displayed as a function of structure for semiconducting nanotubes (after [1.125]) (**HOPG**: highly oriented pyrolytic graphite; **SWNH**: single-walled nanohorn) ►

alkali ligands, which has been suggested for use as an effective hydrogen storage material (Fig. 1.15b) [1.134].

Carrying out covalent chemistry of **SWNTs** is necessary for achieving properties important for the formation of composites, preparation of solutions, etc. [1.135]. In most cases, the first chemical reaction aims to break the strong carbon–carbon sp^2 bonds in the sidewalls of the nanotubes by oxidation or fluorination. Afterwards, the attached OH or F groups can be substituted with alkyl or aromatic groups. Figure 1.15 shows different kinds of nanotube reaction products. Various groups can be introduced onto the sidewall or defect locations in the sidewall, or in the cap; surfactants or polymers can be attached to the surface via noncovalent bonds, and the cage of the nanotube can also be filled with different chemicals (in this schematic, C_{60}).

Producing nanotubes with given chirality by direct growth or separation methods is still an underdeveloped area and a challenging task. Functionalization of metallic nanotubes [1.136] with side-groups, which makes them heavier than unfunctionalized semiconductor nanotubes, offers a way for more selective and higher yield separation.

Another important area of nanocarbon chemistry is the oxidation, reduction, and functionalization of

graphene. Graphite oxide is often produced to aid exfoliation of layers of graphene into graphene oxide (GO), after which reduction procedures are needed to yield graphene as a product (reduced graphene oxide, RGO) [1.137, 138]. Figure 1.15d displays the consecutive steps applied in one of the possible reduction procedures of GO, as well as a photo of the solutions at each step and the C 1s x-ray photoelectron spectroscopy (XPS) peak in the spectra of these materials.

1.3.7 Behavior of Nanomaterials in Corrosive Environments

Some of the ancient and medieval applications of nanomaterials pointed towards corrosion prevention. The Chinese *heiqigu* are black bronze mirrors with a surface coating made of SnO₂ nanoparticles, most probably doped with Cu, Fe, Pb, and Si [1.145, 146]. Similarly, as mentioned in Sect. 1.1.1, Mayan blue paint was not only a rare and beautiful color for its time, but also had corrosion resistance and retained its properties for centuries while buried in soil [1.7].

Figure 1.16a shows an example of preventing an aluminum alloy from corroding in an NaCl-containing water environment [1.147]. The scanning electron microscopy (SEM) and TEM images show the morphology of halloysite (aluminosilicate) nanocontainers which hold and release anticorrosion agents, normally polymers, onto the surface when the pH of the environment changes. The photos show extensive surface corrosion of the specimen in a dilute solution when coated without the nanomaterial included but minimal damage in ten times higher concentration salt solution with the filled halloysite additive.

Superalloys are designed and manufactured not only for mechanical strength and creep resistance but also to avoid corrosion in high temperature and harsh environmental conditions. They themselves may or may not consist of nanostructured materials. Figure 1.16b shows an effective nanomaterial coating for corrosion prevention of a Ni superalloy (K52) [1.148] deposited by sputtering a nanostructured layer of the same alloy

Fig. 1.14a–d Thermal properties of nanomaterials. **(a)** Melting point of gold nanoparticles as a function of size, showing decrease with smaller sizes (after [1.90, 126]). **(b)** Melting point of indium nanograins in aluminum matrix; the direction of deviation from the bulk value depends on the method of preparation (after [1.139]). **(c)** Thermal conductivity of SWNTs and graphene. The thermal conductivity of aligned nanotubes is within an order of magnitude of in-plane values for graphite or diamond (after [1.140, 141]). Raman shift of the G peak position of a graphene sample versus change in total dissipated power. Values calculated for thermal conductivity are higher than for CNTs (after [1.142]). **(d)** Pillared graphene structure proposed originally for hydrogen storage (after [1.143]). Thermal conductivity of the structure along the graphene plane direction is decreased while the vertical thermal conductivity is increased by increasing the number of pillars (after [1.144]) ►

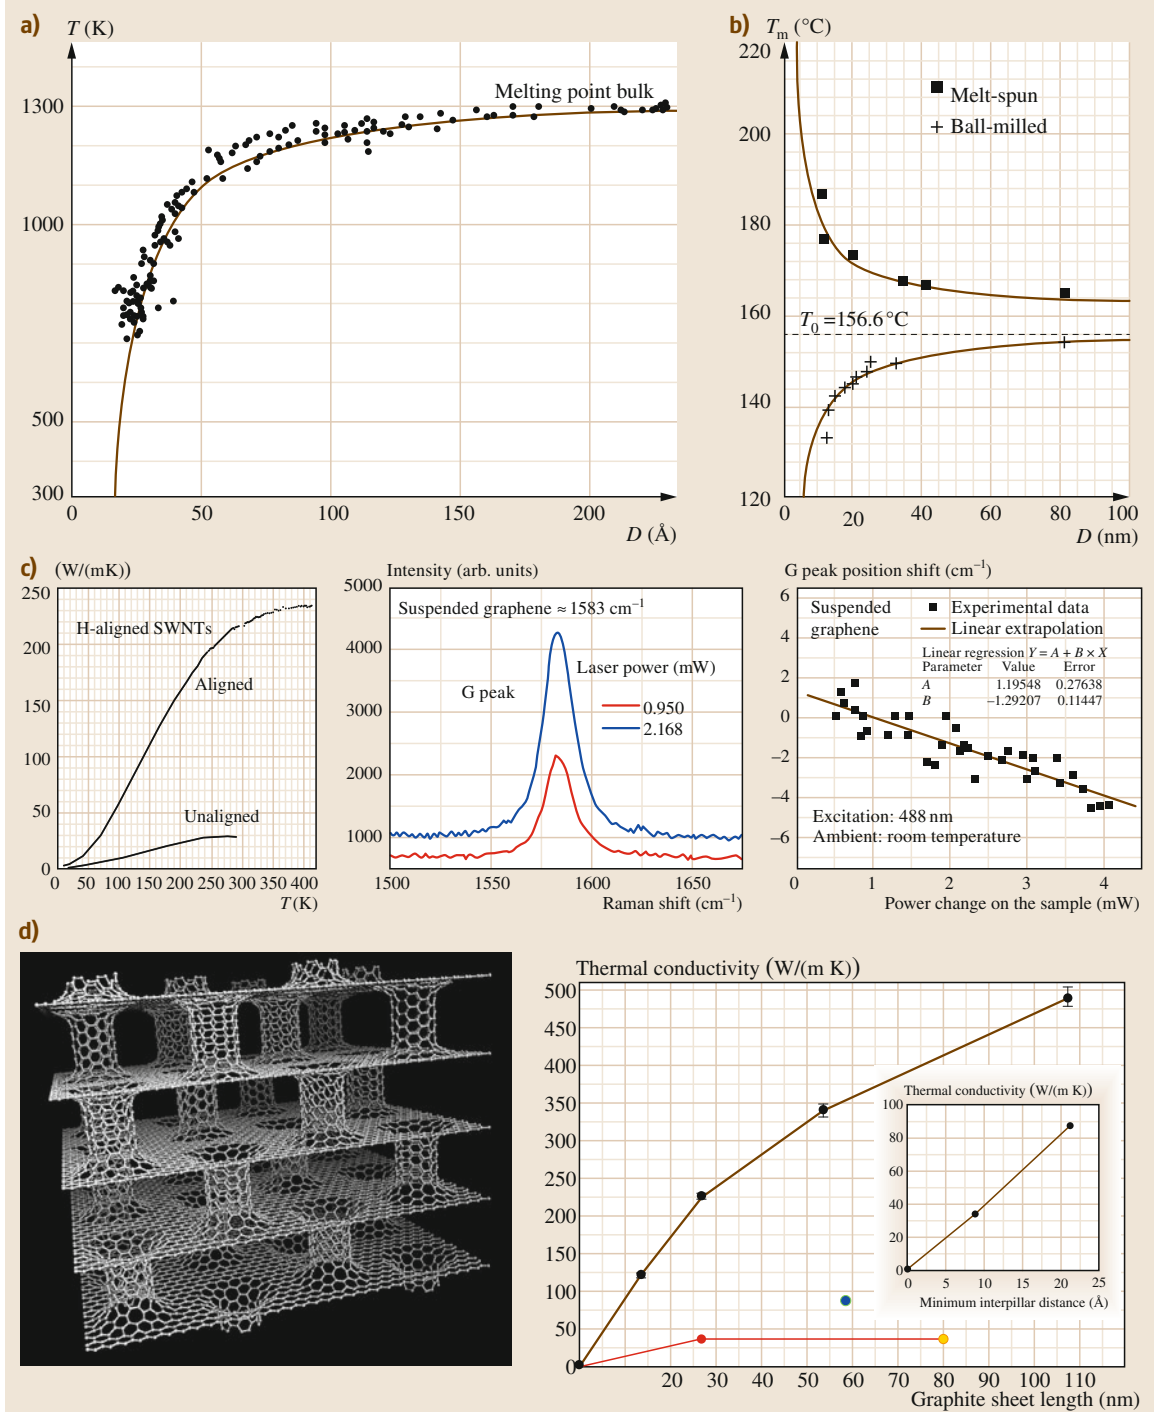

onto the surface of the specimen. The SEM and TEM images show the morphology of the deposited layer; it has a microgranular structure built up from sub-10 nm particles. The samples were oxidized in air at high temperature, and the oxidation kinetics showed parabolic growth of the oxide layer (Wagner regime) for both the uncoated and coated alloy, however the rate of oxidation was higher for the uncoated sample at all temperatures investigated. The surface of the oxidized sample was coated by nanowire structures, mainly alumina and TiO₂ nanowires, while the uncoated sample had a microgranular oxide layer. In a hot salt environment, the trends were different: the coated sample started to corrode faster, and after an initial fast scaling, the process slowed down.

In several cases, nanomaterials exhibit the same or worse corrosion resistance than bulk materials. This effect is mainly attributed to the high concentration of defects in these nanoparticles and nanowires. In [1.149], silver nanowires were investigated, and the authors found faster sulfide formation in nanowires than for bulk silver and that the reaction mechanism was the same.

1.4 Typical Applications of Nanomaterials

Nanomaterials are not a sanctified object of nanoscience; they have already found applications in a very wide range of engineering fields. From mechanical

engineering to bioengineering, we use nanomaterials regularly in our computers, stain-resistant clothes, and suntan creams. Other applications such as nanomaterial-

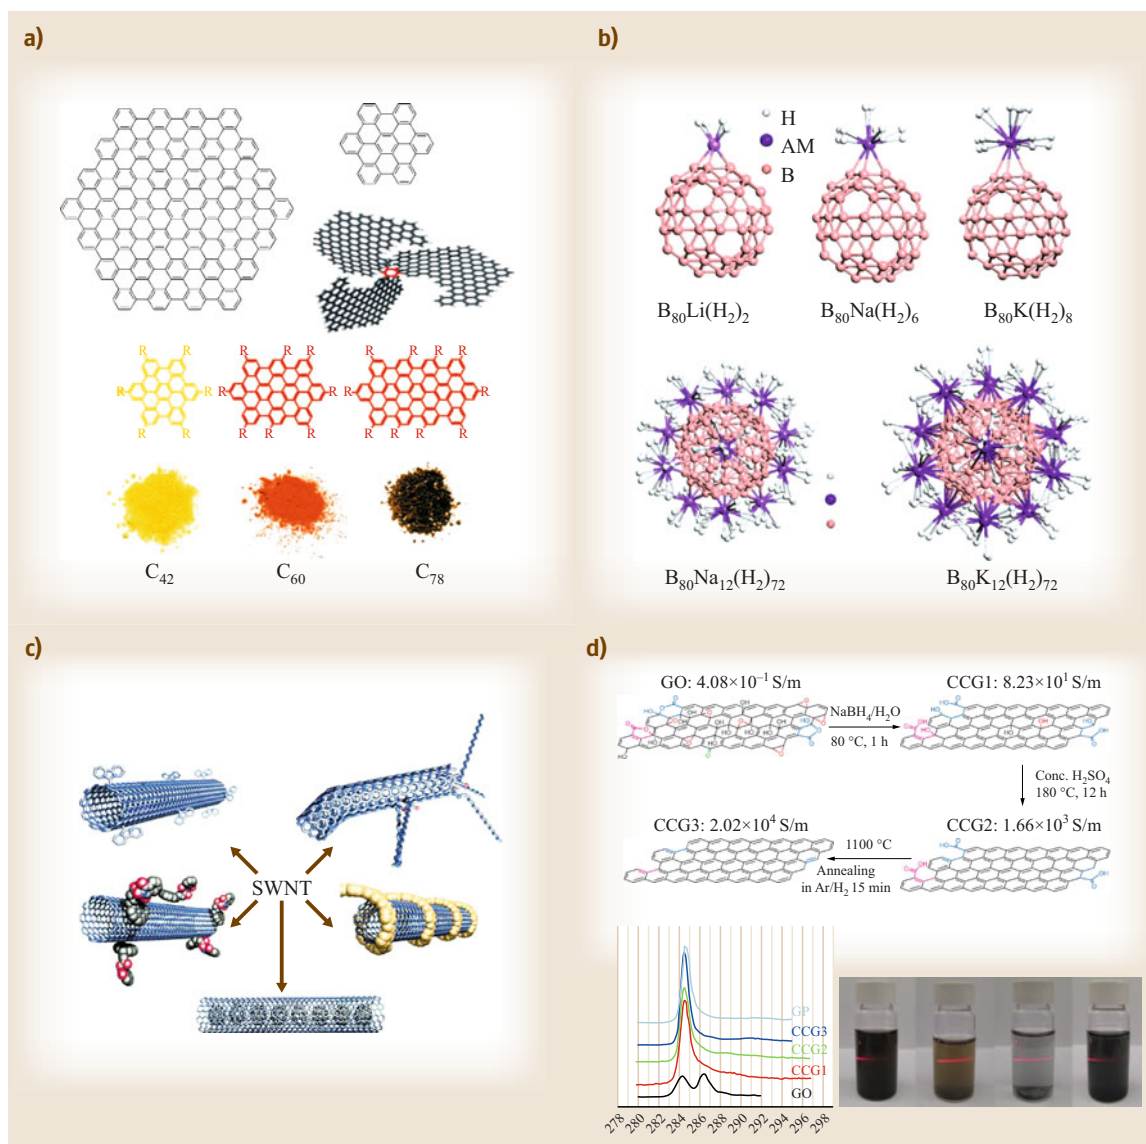

Fig. 1.15a–d Chemical properties of nanomaterials. **(a)** Graphene molecules demonstrating various sizes and shapes. Graphene molecules are mostly 2-D materials; however, they can be organized into larger, 3-D structures; a *nanopropeller* is shown as an example. The size dependence of the color of planar polycyclic aromatic hydrocarbons (PAHs) is also demonstrated (after [1.132]). **(b)** Modifications of the B_{80} molecule by forming complexes with alkali elements. The complexes are suggested as effective hydrogen storage materials up to 11 wt. % capacity (after [1.134]). **(c)** Various ways of functionalization of SWNTs: attaching molecules to the defect locations in the side-walls, connecting molecules by covalent bonds, functionalization with surfactants, functionalization with polymers, and endohedral functionalization with fullerenes (after [1.150]). **(d)** Steps of a GO reduction procedure showing the schematics, the corresponding bonding energies in XPS, and photos of the solutions for each step. The vials contain GO in deionized (DI) water, GO in dimethylformamide (DMF), CCG3 (CCG: chemically converted graphene) in DI water, and CCG3 in DMF from left to right (after [1.137]).

Photos of aluminum specimens after 2 weeks of exposure to corrosive medium (bottom row): a1) blank aluminum alloy immersed in 0.3% NaCl, a2) blank aluminum alloy immersed in 0.3% NaCl saturated with 2-mercaptobenzothiazole, and a3) aluminum alloy coated with halloysite-doped sol-gel film after immersion in 3% NaCl solution (after [1.147]). **(b)** Top row: Layers of nanostructured materials on its bulk substrate for K52 alloy. SEM images for top b1) and cross-section b2) morphologies are shown along with the TEM showing the structure of the sputtered nanocoating b3). Bottom row: Oxidation kinetics of the bulk and coated alloys exhibited faster oxidation rate for the bulk samples at the three temperatures (800 °C, 900 °C, 1000 °C) investigated (after [1.148])

filled composites and medicines released from nanocapsules will soon belong to this category. In scientific communications, a vast number of applications have been proposed in diverse fields. Several chapters in the final part of this handbook are devoted to applications, and in all the other parts, each chapter contains a short section showcasing applications of the nanomaterials considered. Here, we provide only a glimpse on applications, grouped into the categories of catalysts and catalyst templates, nanomaterials in energy conversion, and storage and sensors based on nanomaterials.

1.4.1 Catalysts and Catalyst Templates

Heterogeneous catalytic reactions need high surface area for obvious reasons, as the process can be realized only at surfaces, and all materials in the volume represent unnecessary weight and cost. There is another reason why nanomaterials can behave differently from their larger-grain counterparts; i.e., they have different selectivity features. In surface catalysis it is well known that different crystal planes and different defect sites on the surface (e.g., steps, kinks) promote different reactions for the same conditions [1.151]. It has also been pointed out that, in homogeneous catalysis, edge and corner atoms play an exceptional role; however, their ratio can change during the reaction, and in fact surface reconfiguration is common [1.155]. In nanomaterials, the number of this kind of defects is naturally higher, depending also on their size and shape, so control of these parameters provides well-regulated reactions in a multichannel process. Figure 1.17a displays an example of how the size and shape of platinum nanoparticles govern the completeness of a pyrrole hydrogenation reaction [1.151]. Figure 1.17b shows how the size of a cobalt catalyst changes the yields of Fischer–Tropsch synthesis [1.152]. The yield is proportional to the dispersion of cobalt atoms, and the site-time yield is accordingly constant, which means that the size of the particles has an important effect; however, it does not change the surface features, so the authors could not find a shape dependence

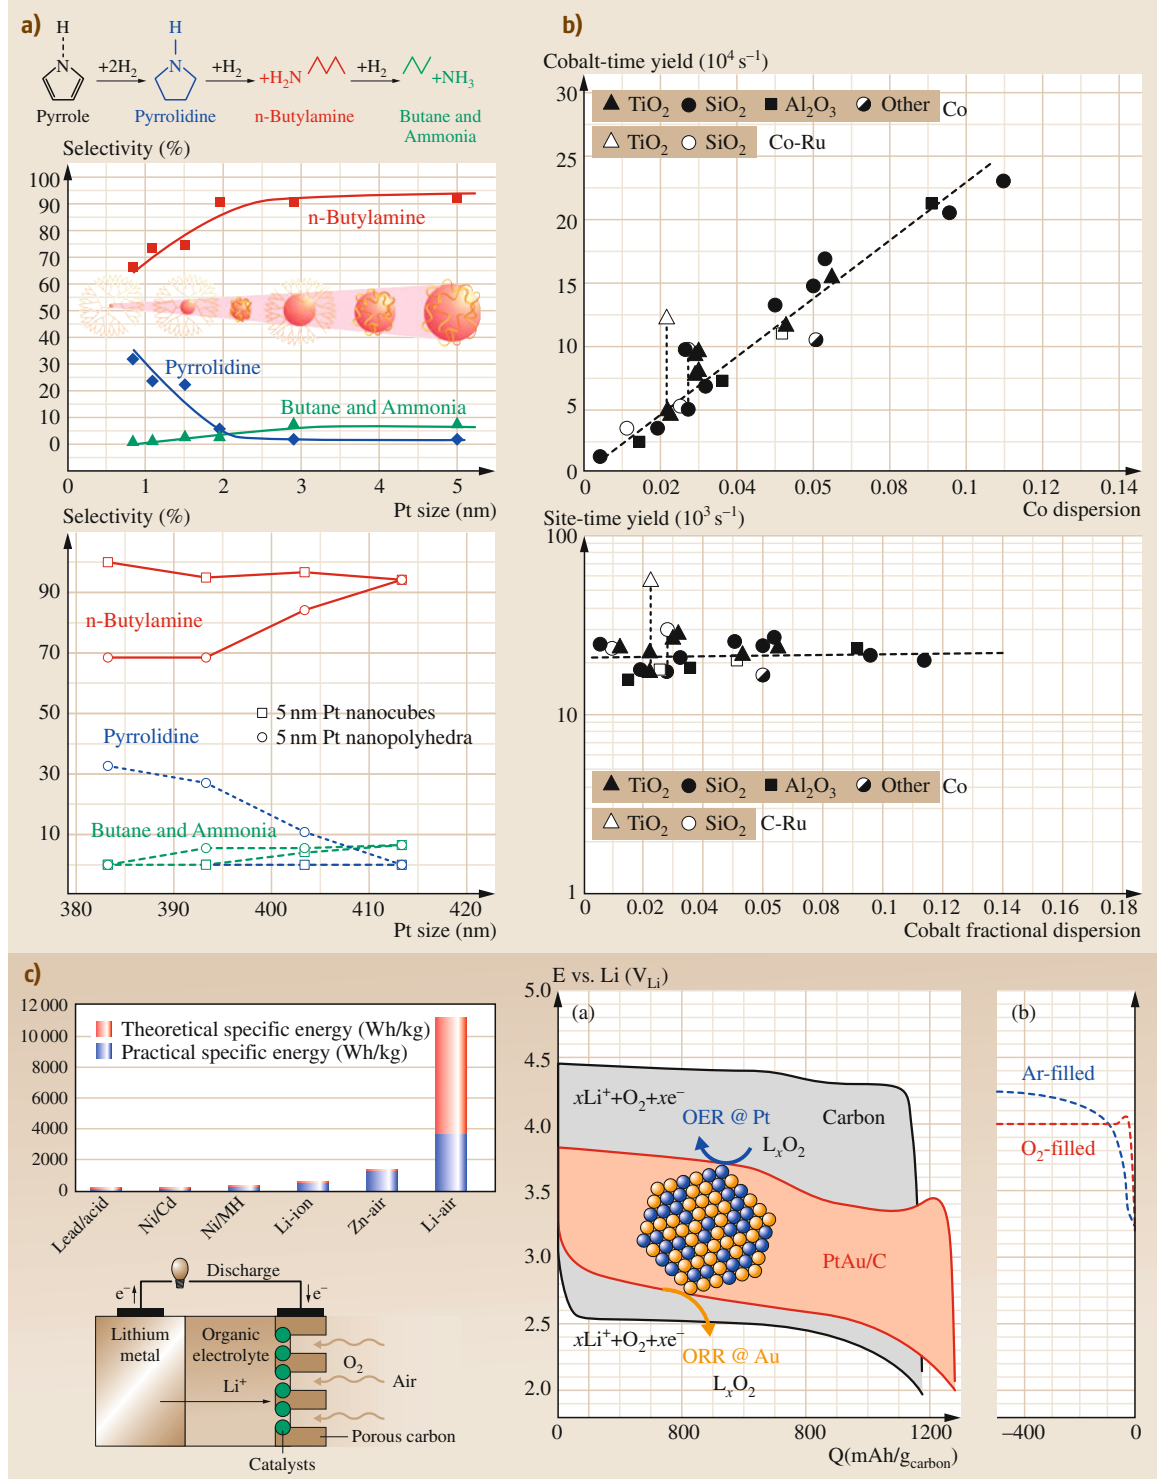

Figure 1.17c introduces a specific, electrochemical, use of gold–platinum nanocatalyst used in Li–air and Zn–air batteries [1.153]. It is clear that these batteries have much higher specific energy storage capacity than conventionally used ones. The battery works similarly to Li-ion batteries inside, however they have a special porous anode where the air – in some cases oxygen or ozone – enters. Here, a catalyst is needed for efficient

conversion of Li ions to lithium oxide during discharging, and lithium oxide to lithium ions during charging of the battery. In the nanosized alloy catalyst the platinum part is responsible for the reduction reaction and the gold part helps the oxidation.

1.4.2 Energy Conversion and Storage

Harvesting clean energy – mainly by converting naturally present energy to electricity – from abundant resources is one of the most important tasks to be accomplished by modern engineering. As clean energy sources (e.g., solar, wind) are not correlated with energy demand in time and non-localized energy sources are needed in transportation, too, efficiency in both energy harvesting and energy storage is necessary. Energy harvesting involves macroscopic equipment, e.g., wind turbines, however in many methods nanomaterials are used to improve efficiency. The two most relevant fields are thermo- and piezoelectric conversion and solar energy conversion by solar cells. Thermoelectric nanomaterials convert thermal energy between two locations at different temperatures. The measure of the efficiency of a material in thermoelectric conversion is the *ZT* parameter, the ratio of the Seebeck coefficient and the thermal and electrical conductivity of the material. Superlattices are the most efficient conversion devices, however their fabrication is costly and scaling up is complicated. Work has been carried out for efficient use of simpler systems, e.g., silicon nanowires [1.79]. Another way to apply nanomaterials in energy conversion is by using quantum dots – nanoparticles – in solar cells in order to trap more photons or capture more energy from photons [1.156]. Particular cases of

Fig. 1.17a–c Application of nanomaterials as catalysts. **(a)** Pyrrole hydrogenation reaction catalyzed by platinum nanoparticles having different size; the reaction product is a mix of pyrrolidine and *n*-butylamine for small (1–2 nm) particles and mostly *n*-butylamine for larger (3–5 nm) particles; the amount of butane and ammonia slowly increases with increasing particle size (after [1.151]). **(b)** CO conversion time yield and turnover rate in a Fischer–Tropsch reaction as a function of cobalt dispersion [1.152]. **(c)** Energy density for several commonly investigated batteries; schematic of a possible configuration for Li–air or Zn–air battery, showing the location of the catalyst; charge–discharge characteristics of a Li–air cell displaying the role of the PtAu catalyst particle in the reduction and oxidation steps (ORR: oxygen reduction reaction; OER: oxygen evolution reaction) (after [1.153, 154]) ►

clean energy conversion that use nanomaterials are displayed in Fig. 1.18a. The measurements show a strong dependence of the reduction rate achieved with TiO_2 on the gold particle size; the gold template modifies the Fermi level, and the shift in the Fermi energy increases with decreasing particle size. This reaction is used in photoelectrochemical energy conversion. It was also shown that the solar energy conversion is dependent on the configuration of the optically transparent electrode ($\text{OTE}/\text{SnO}_2/(\text{H}_2\text{PC}_n\text{MPC} + \text{C}_{60})_m$), where the length of the linker (the number of fullerene molecules) plays the most important role [1.72]. For energy storage, we have collected examples from our previous work in Fig. 1.18b. The SEM images show an MnO_2 structure prepared by hydrothermal synthesis [1.73]. The nanowires obtained have potential applications in supercapacitor devices. We also present an atomically thin, transparent, flexible supercapacitor based on single- or few-layer graphene electrodes. The transparency of the GO and RGO layers are demonstrated placed them onto a printout; here the thickness of the multilayered films was set to $\approx 10\text{ nm}$ by consecutive dip-coating steps. The last part (Fig. 1.18b) shows a supercapacitor array designed on a monolithic GO piece. Parts of the GO were reduced by a laser beam, and these RGO parts serve as electrodes while the unreduced GO acts as a solid electrolyte.

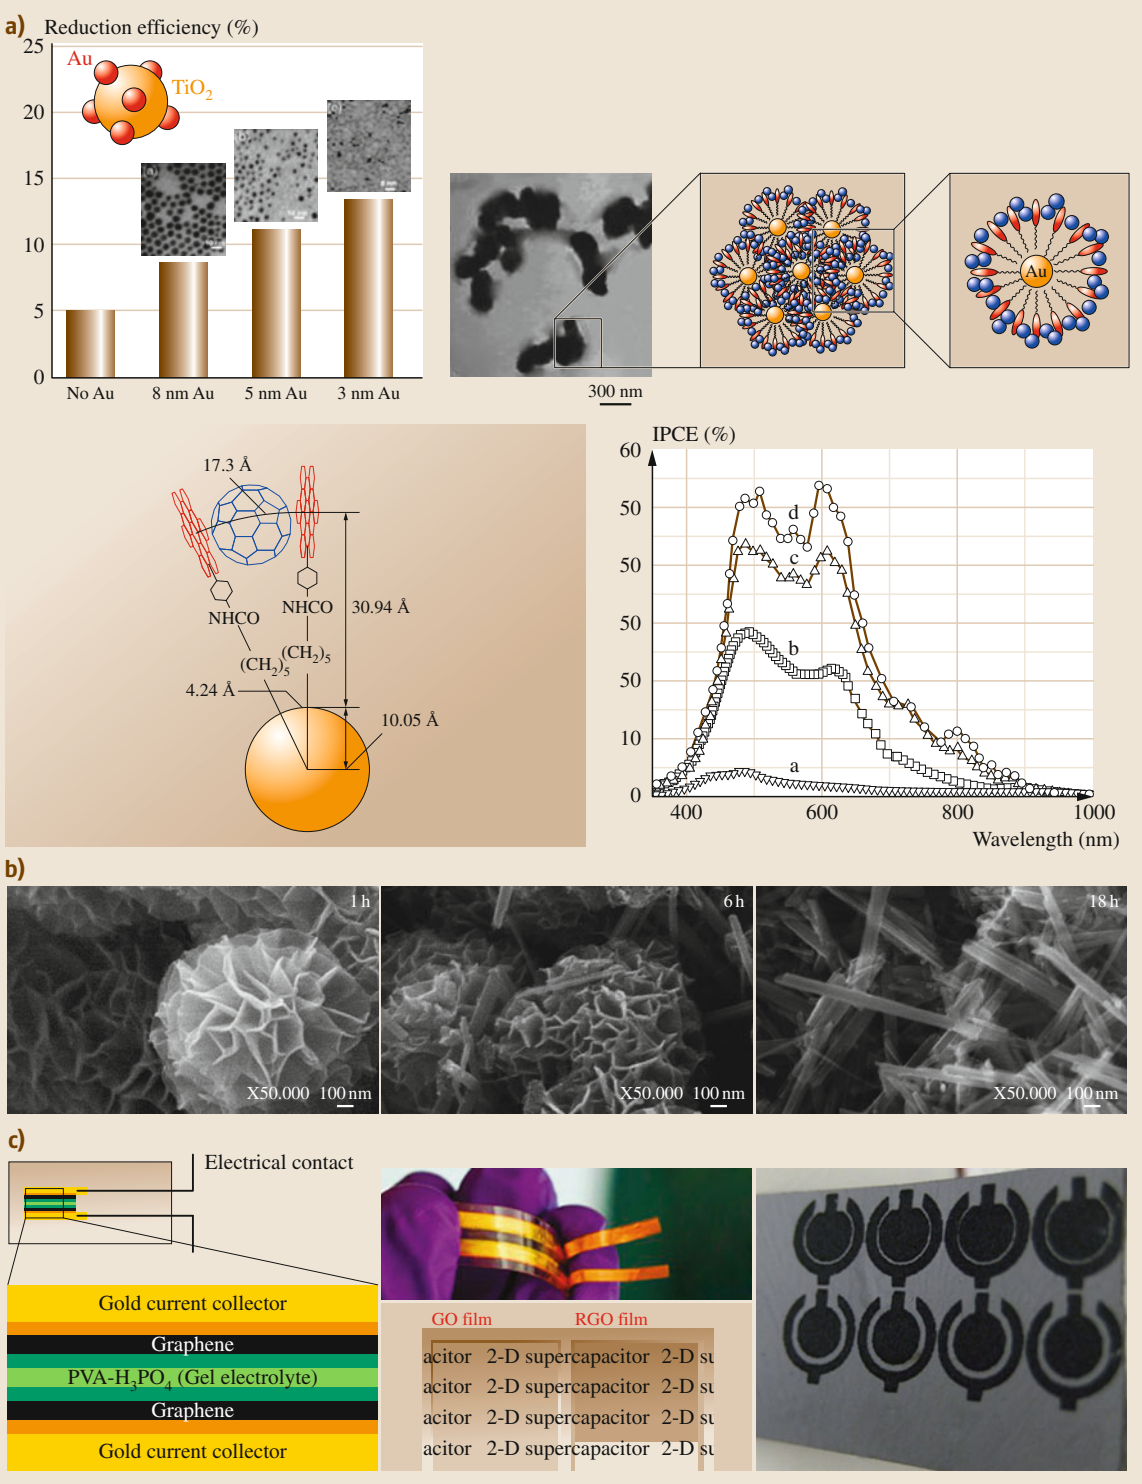

1.4.3 Sensors Based on Nanomaterials

Nanomaterials are excellent choices for use as active elements of chemical (gas) sensors. To achieve high sensitivity, the material needs to have high dispersion, as surface atoms interact and undergo changes whereas atoms inside the material do not change, meaning that, the higher the surface atom ratio, the larger the relative change in the measured physical property of the material. Similarly to applications as catalysts, in sensors not only the size of the particles is important but also their shape. As the shape, number, and configuration of edge and corner atoms change, further differences occur in the signals measured. Figure 1.19a demonstrates the effect of various shapes when nanoparticles, nanowires, and nanoplatelets of tungsten oxide were used [1.77]. In this case, the nanowires have the highest sensitivity, followed by the platelets and finally the nanoparticles.

Fluctuation-based sensing or fluctuation-enhanced sensing (FES) provides selectivity via investigation of fluctuations in resistance, voltage or current. The

Fig. 1.18a–c Application of nanomaterials in energy conversion and storage. **(a)** Dependence of photoreduction efficiency of TiO_2 particles on the size of a gold nanoparticle used as a substrate. The smaller the particle, the higher the reduction efficiency. Schemes of $(\text{H}_2\text{PC}_n\text{MPC} + \text{C}_{60})_m$ configurations are also displayed. These particles are applicable for photo-induced current; the photocurrent for the visible spectrum is displayed for different configurations of the structure of $\text{OTE}/\text{SnO}_2/(\text{H}_2\text{PC}_n\text{MPC} + \text{C}_{60})_m$ with parameters of $[\text{H}_2\text{P}] = 0.19\text{ mM}$, $n = 15$, $\text{C}_n = [\text{C}_{60}] = 0.38\text{ mM}$ (after [1.72, 74]). **(b)** Evolution of MnO_2 morphology as a function of the dwell time of hydrothermal synthesis. Supercapacitors prepared with nanowire electrodes have $150\text{--}200\text{ F/g}$ specific capacitance (after [1.73]). **(c)** Physical appearance of nanomaterial supercapacitors; transparent, flexible supercapacitor with graphene electrodes (after [1.75]) and laser-defined GO electrode–RGO electrolyte (after [1.76]) (IPCE: incident photon to charge carrier efficiency; PVA: polyvinyl alcohol) ►

method is based on measurement of a signal as a function of time, analysis of this signal, and in most cases fast Fourier transformation (FFT), and finally interpretation of the power spectral density in characteristic frequency ranges to identify the chemical environment [1.78, 81]. This interpretation can be a simple linearization, application of a neural network, or use of principal component analysis (PCA) plots. All these interpretation methods allow selectivity for different gases and for different concentrations. Any kind of sensor can be essentially used with this method; however, sensors made of nanomaterials have the advantage of much stronger FES signals and significantly more information content [1.80, 82, 83]. Carbon nanotubes are especially useful and important building blocks of FES devices, as they can be functionalized with appropriate chemical groups that make them selective for particular materials [1.84]. Functionalization is especially well studied in the case of CNTs for use in biosensors [1.85]. Figure 1.19b displays a print made with a carbon nanotube ink. A similar printing method and ink were used to create the sensors for the devices providing the signals in the lower row. The fluctuation power spectra were measured using a Taguchi-type sensor, and show measurable differences between three different gases compared with a synthetic air reference. The PCA plots demonstrate the sensitivity and selectivity of the printed carbon nanotube sensors. Signals of 30 ppb concentration are shown to be selective for the measured gases.

1.5 Concluding Remarks

Nanomaterials differ in many regards from their macroscopic – bulk – allotropes, and accordingly they call for special scientific and engineering approaches. The large number of scientific articles, encyclopedias, and handbooks in related topics, as well as textbooks and full courses, show the growing importance of this field.

In this chapter we could give only a glimpse of the numerous unique and interesting, mainly universal properties of nanosized materials. This similarity of

properties of materials as a function of their characteristic size clearly shows that nanomaterials represent a one-of-a-kind, coherent group of materials. The later chapters in this handbook elaborate on the synthesis, specific properties, and applications of the various material groups. Our main objective in this chapter was to collect and present material properties in a way that would introduce novice readers to a new topic, and at the same time serve as a reference for the everyday work of well-established scientists and engineers.

1.6 About the Contents of the Handbook

The structure of the handbook follows the classification of important material groups. Part A describes carbon-based nanomaterials from fullerenes to nanotubes and nanofibers, as well as nanodiamonds. Part B introduces noble and common metals and alloys. Part C describes ceramic materials, crystalline and glassy oxides, and other compounds. Part D describes composites and hybrid structures where nanomaterials serve as fillers

and building blocks, as well as solutions, so-called nanoinks. Part E deals with porous nanomaterials, metals, ceramics, and silicon. Part F presents examples of organic and bio-nanomaterials, bones, and fibers. Finally, Part G contains several chapters on the topics of applications in nanomedicine, civil engineering, toxicology, and hazards, as well as energy harvesting and energy storage.

2. Graphene – Properties and Characterization

Aravind Vijayaraghavan

Graphene is the two-dimensional allotrope of carbon, consisting of a hexagonal arrangement of carbon atoms on a single plane. This chapter explores the history of graphene, as the theoretical building block for other carbon allotropes as well as its rise as a material in its own right in recent years. Graphene can be fabricated by different methods including mechanical exfoliation, chemical vapor deposition, and decomposition of SiC, although bulk-quantity production of pristine graphene remains a challenge. The atomic and electronic structure of graphene is described, highlighting the strong correlation in graphene between structure and properties, as is the case with other carbon allotropes. Graphene exhibits a number of unique and superlative electronic and optical properties. The intrinsic properties of graphene can be tailored by nanofabrication, chemistry, electromagnetic fields, etc. Various applications of graphene have been proposed in electronic, optoelectronic, and mechanical products. In addition, graphene has emerged as a candidate in chemical, biochemical, and biological applications. Derivatives of graphene such as graphene oxide or graphane are also of interest in terms of both fundamental properties and applications.

As a three-dimensional (3-D) material, carbon exists as three predominant allotropes: diamond, graphite, and amorphous carbon (historically known as carbon black). These are distinguished by their crystalline structure and the hybridization of the carbon atoms therein.

Carbon atoms in diamond are all sp^3 hybridized and arranged in diamond cubic structure which comprises two interpenetrating face-centered cubic (fcc) lattices. Graphite has a layered structure, where the sp^2 hybridized carbon atoms are arranged in a hexagonal

Fig. 2.1a–d Allotropes of sp^2 carbon: (a) graphite (3-D), (b) graphene (2-D), (c) carbon nanotube (1-D), and (d) fullerene (0-D) (courtesy K.S. Novoselov)

lattice in each plane, while the planes themselves are AB (Bernal) stacked and held together by van der Waals forces. Amorphous carbon, as the name indicates, does not have long-range crystalline order, although locally the atoms are bound together covalently and comprise a mix of sp^2 and sp^3 carbons. While diamond can be reduced in size to the nanoscale to form nanodiamond, it is graphite that can be truly reduced to lower-dimensional allotropes. A single layer of graphite is defined as graphene, the topic of this chapter. Graphene has been used as the building block to conceptually visualize carbon allotropes such as graphite, carbon nanotubes, and fullerenes; it was believed that such a freestanding, two-dimensional (2-D) structure would not be stable. Carbon nanotubes (CNT) form its one-dimensional (1-D) counterpart, while fullerenes are the zero-dimensional (0-D) allotropes. These various forms of carbon are summarized in Fig. 2.1. It is important to note that CNTs or fullerenes are not unique structures, but rather describe a family of structures, which are described in detail in subsequent chapters. Nonetheless, their structure and properties are all derived from graphene.

Despite serving as the fundamental building block for these carbon allotropes, graphene remained a concept until 2004. It was substantially predated by its related allotropes, fullerenes being discovered and described in 1985 [2.1], while carbon nanotubes were synthesized and their atomic structure elucidated in 1991 [2.2]. The term “graphene” was coined in 1987 [2.3], to describe one of the two alternating layers in graphite intercalation compounds (GIC), the other layer being the intercalating agent. It was postulated that independent, freestanding graphene would not become a physical reality since it would voluntarily transform into a more stable allotrope in an attempt to minimize its surface energy. Supported monolayers of carbon, how-

ever, had been previously synthesized and described, including epitaxial graphene which has been known since the 1970s. Chemical derivatives of graphite such as graphite oxide can be traced back to the 1950s and can exist as single layers (graphene oxide), although these are not truly two-dimensional layers due to out-of-plane atoms which stabilize their structure.

Since graphene occurs naturally as a constituent of bulk graphite, it appeared to be the logical place to start the hunt for freestanding graphene. This effort culminated in the successful exfoliation of a single sheet of carbon atoms by *Andre Geim* and *Kostya Novoselov* at the University of Manchester in 2004 [2.4], using a technique referred to as micromechanical cleavage, or colloquially, the Scotch tape method. This discovery and the subsequent investigations into the properties of graphene were rewarded with the Nobel Prize in Physics in 2010 for Geim and Novoselov. The existence of graphene, however, does not contradict the physics that predicted that it could not exist. It was discovered that graphene is not truly flat; there exist atomic-scale ripples in the carbon sheet, which accommodate the excess surface energy, thereby stabilizing the 2-D structure of graphene. For this reason, it might be argued that graphene is a quasi-2-D material. However, it has been shown to exhibit a range of properties that are unique to 2-D physics, and therefore graphene will be identified as a 2-D material for the rest of this chapter, without qualification.

A surge of research into the structure and properties of graphene ensued, and graphene did not disappoint. Almost immediately, an anomalous quantum Hall effect was reported in graphene, which also serves as direct experimental evidence for the electrons in graphene behaving as massless Dirac fermions, confirming theoretical predictions. Graphene yielded record high values for various properties, such as tensile strength, car-

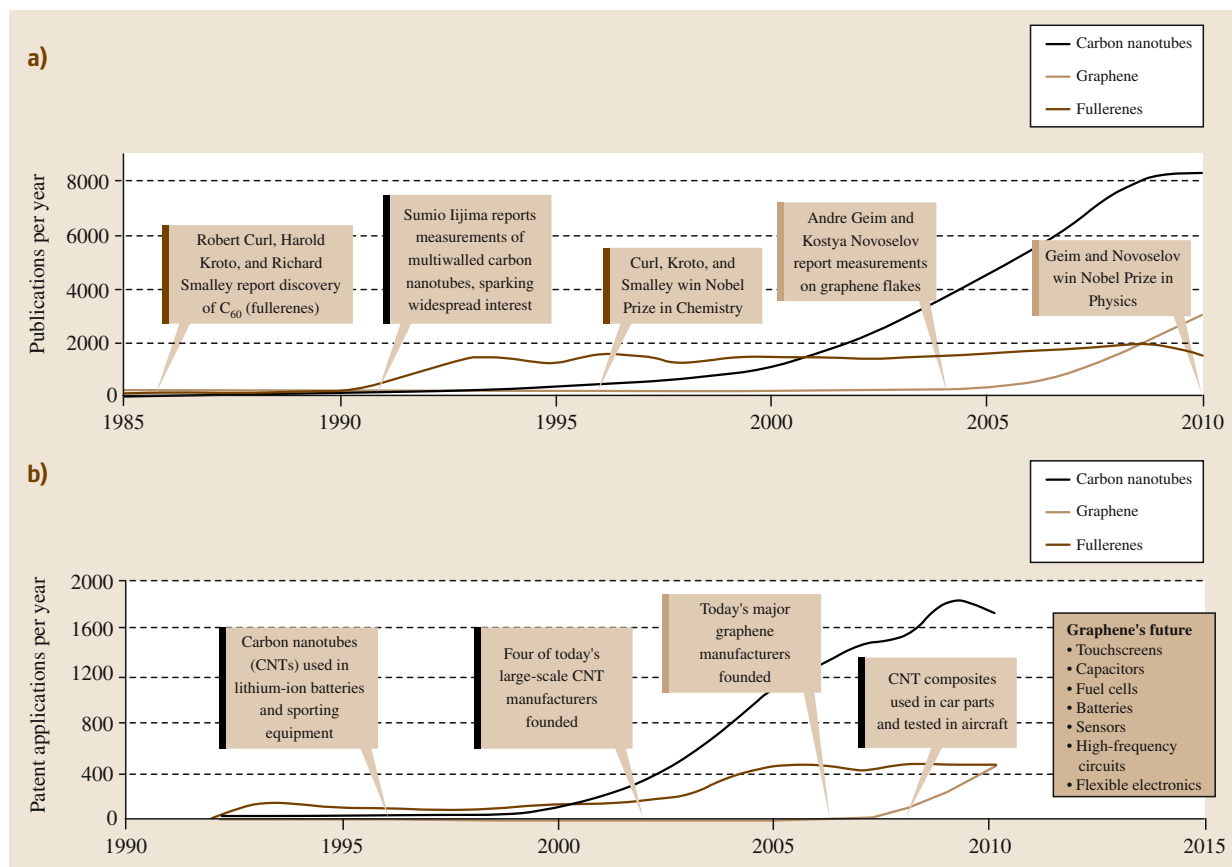

Fig. 2.2a,b Time line of nanocarbon allotropes and the (a) number of publications and (b) number of patent applications per year on each topic (after [2.5])

rier mobility, thermoelectric power, etc. Scientists have also succeeded in transferring epitaxial graphene from its native metal or silicon carbide substrate onto other substrates of interest or as freestanding structures. Since the early 1990s, carbon nanotubes have been described as *rolled-up graphene sheets*. This description has come full circle, with the recent unzipping of carbon nanotubes to yield graphene. While the number of publications on carbon nanotubes has leveled off in recent years at about 8000 papers per year, the publications on graphene are only just starting their exponential growth at a rate faster than that which was enjoyed by carbon nanotubes in their first few years (Fig. 2.2; over 3000 papers were published in the field of graphene in 2010 [2.5]). A similar trend is also observed in patent applications based on carbon nanotubes and graphene.

Any chapter on graphene would not be complete without discussion of its other, quasi-2-D derivatives based on the fundamental graphene structure. Perhaps the most interesting of these is the case where two graphene layers are AB stacked to form a bilayer. Unlike graphene, which has zero electronic bandgap and is therefore a quasimetal, this bilayer structure can have a bandgap. A bandgap is critical for electronic applications, and one of the most active areas of research in graphene is currently the generation of a stable, true, electronic bandgap in graphene. The oxidized derivative, graphene oxide (GO), has been alluded to before, and serves as a useful intermediate in a chemical route for graphite exfoliation. Hydrogenated graphene, christened graphane, and fluorinated graphene or fluorographene have been recently produced and characterized.

2.1 Methods of Production

Historically, graphene supported on substrates such as metals and SiC was synthesized first; however, such graphene was not liberated from the substrate support to form a truly two-dimensional structure. Freestanding graphene was not a reality until the ground-breaking publication of Novoselov and Geim in 2004. Consequently, this micromechanical cleavage method is presented first, followed by the epitaxial synthesis of graphene as well as chemical vapor deposition on metallic substrates. Graphene can also be exfoliated from graphite by sonochemical means in a solvent, followed by a purification step to extract the monolayers. Recently, islands of nanographene have also been synthesized by chemical routes, and this bottom-up approach is discussed. Finally, separate sections are devoted to production of graphene nanoribbons (GNR) and derivatives of graphene.

2.1.1 Micromechanical Cleavage of Graphite (Scotch Tape Technique)

Micromechanical cleavage (or exfoliation), as the name implies, refers to thinning down of graphite by mechanically reducing the number of layers in a repeated fashion. Graphite is known to cleave preferentially along the interlayer direction where layers are held together by weak van der Waals forces, rather than across the strong covalent bonds that bind the atoms within a layer. The most common procedure to accomplish this is using adhesive tape. Attaching a thick graphite flake to adhesive tape on both its exposed faces, and then peeling the two pieces of tape apart, results in two thinner flakes of graphite, stuck to each of the adhesive tape pieces. Repeating this process a sufficient number of times would in principle result in a single sheet of carbon atoms, i.e., graphene, adhered to the adhesive tape. This is still not freestanding graphene, since it is supported by the tape, and must be transferred to a suitable weakly coupling substrate or suspended across supports. The genericized Scotch trademark for transparent adhesive tape has subsequently lent its name to the micromechanical exfoliation of graphite. Different variations of this method exist.

One of the earliest such efforts was undertaken by *Fernandez-Moran*, who succeeded in thinning graphite down to ≈ 15 layers (5 nm) over a millimeter size, to serve as a support membrane for transmission electron microscopy [2.6]. This result remained relatively unknown outside the electron microscopy commu-

nity, until the interest of condensed matter physicists turned to graphene and other lower-dimensional carbons. The first successful thinning down of graphite to its monolayer graphene form involved a wet/dry method [2.4]. The surface of highly oriented pyrolytic graphite (HOPG) was first patterned into square mesas, which were pressed into wet photoresist. After baking, the mesas attached to the now dry photoresist, and could be detached from the bulk of the HOPG. Scotch tape was used to repeatedly peel off layers of graphite from the mesas, thinning them down, until only very thin layers remained in the photoresist. The photoresist was then dissolved in acetone to release these thin flakes, which float on the solvent surface. The flakes were collected onto Si/SiO₂ wafer pieces dipped into the solvent. Thicker flakes adhering to the silicon could be cleaned off by sonication in 2-propanol, while thinner flakes were reported to adhere strongly to the substrate due to capillary forces.

In the resultant sample, the flakes of graphene, bilayer graphene, and few-layer graphene (FLG) must be distinguished from among a sea of flakes of various thicknesses. Fortunately, at certain thicknesses of the SiO₂ layer that covers the silicon wafer, for example, 300 nm, the interference contrast generated by graphene flakes on the surface makes them relatively easy to spot and identify by optical microscopy. A trained eye can, in fact, distinguish between graphene, bilayer graphene, and thicker flakes. This is described in detail in Sect. 2.2.4 on optical properties of graphene. Figure 2.3 shows the appearance of micromechanically cleaved graphene flakes of different thicknesses in an optical microscope [2.7], atomic force microscope (AFM) [2.8], and transmission electron microscope (TEM) [2.9]. These, along with Raman spectral mapping, are routinely used to characterize graphene flakes, and are described in Sect. 2.3 dedicated to graphene characterization.

The procedure has since evolved into a completely dry technique. It has been shown that rubbing the freshly cleaved surface of a layered material such as graphite on another solid surface results in a variety of flakes, among which monolayer flakes can be invariably found [2.8]. Alternatively, HOPG is mechanically cleaved repeatedly between two pieces of adhesive tape until the surface of the tape is covered by a layer of relatively thin graphite [2.10]. No specific criterion exists at the time of writing for the optimum degree of such exfoliation. Researchers rely

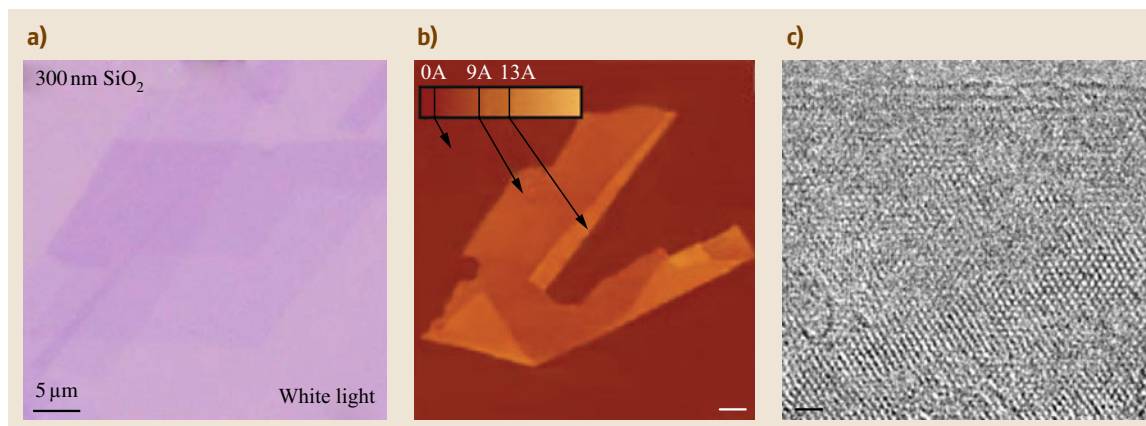

Fig. 2.3a–c Monolayer graphene flake as seen in (a) an optical microscope [2.7], (b) an atomic force microscope [2.8], and (c) a transmission electron microscope (after [2.9])

on personal experience or historic parameters specific to their laboratory to carry out this procedure. Once a satisfactory degree of exfoliation has been accomplished with the adhesive tape, it is pressed against the surface of a desired substrate, such as Si/SiO₂ wafer. Again, various scientist-specific parameters exist for this process, such as duration, force, application and peeling-off procedure, etc. At the end of this procedure, the surface of the graphene as well as the substrate is often contaminated with adhesive residue from the tape, which has been shown to limit the carrier mobility in the graphene flake. Efforts to remove this residue have included annealing at 200 °C in a reducing atmosphere of Ar and H₂ [2.11], annealing in vacuum at 280 °C [2.12], and current-induced Joule heating after graphene device fabrication [2.13]. Variations such as applying an electric field perpendicular to the substrate during the transfer from the adhesive tape have also been explored [2.14]. Covalent linkers such as perfluorophenylazide between graphene and SiO₂ have been explored to aid in the exfoliation process to increase monolayer yield [2.15]. The residue issue can also be completely avoided by evaporating a thin film of gold on the HOPG surface prior to the transfer step, to avoid direct contact between the adhesive and the graphene [2.16]. The gold can be subsequently dissolved in a suitable etchant without affecting the graphene. The lack of standardization is indicative of the early stage of current graphene research, and is perhaps an indication that micromechanical exfoliation is not destined to evolve into a large-scale or industrial method for graphene production. Competing techniques, discussed subsequently, have reached much

higher degrees of standardization and reproducibility, albeit with drawbacks of their own.

It should be noted that the *best quality* of graphene currently available is indisputably that produced by micromechanical cleavage, where the graphene quality is defined in terms of crystalline domain size, number of defects, carrier mobility, etc. The choice of initial graphite material having large grain size, using freshly cleaved graphite for further exfoliation, and the cleanliness and quality of the adhesive tape and SiO₂ substrate are all variables which significantly affect the quality of the final flakes obtained. Flakes of graphene hundreds of μm across are routinely produced in laboratories all over the world by this method, predominantly for fundamental research purposes. In some cases, millimeter-size flakes have also been reported. While this method has not matured for commercial applications, ventures such as Graphene Industries have been established to sell micromechanically cleaved graphene flakes.

2.1.2 Chemical Vapor Deposition (CVD)

The study of the deposition of thin graphitic layers on metal substrates by CVD dates back to the late 1960s [2.17, 18]. One of the motivations for this was in fact to eliminate the formation of graphitic structures on metals such as platinum which results in degradation of catalytic activity. CVD is currently the preferred route for large-scale fabrication of carbon nanotubes, and therefore has generated substantial excitement as a potential method for large-scale production of graphene. In general, this involves thermal decomposition of

gaseous hydrocarbon sources followed by dissolution and recrystallization of the cracked carbon on the surface of metallic substrates. The solubility of carbon in various metals, such as rhodium, ruthenium, iridium, and rhenium, has been measured [2.19], along with the observation that excess carbon dissolved in such metals at high temperatures can segregate as graphite on the surface upon cooling. Various metallic substrates and carbon feedstock have been explored in the effort to grow monolayer graphene, and some of the significant developments are mentioned next.

As early as 1991, monolayer graphene was grown on Pt(111) by hydrocarbon decomposition at 800 °C [2.20], resulting in islands of 20–30 nm size distributed uniformly over the surface. Upon annealing at higher temperatures, the graphene was found to accumulate into large, regularly shaped islands on terraces and step edges. Recently, a variation in which a beam of methane molecules with high kinetic energy (670 meV) impacting a Pt(111) surface at 890 K resulted in large domains of monolayer graphene covering the entire Pt surface [2.21]. Ni soon followed, requiring a minimum temperature of 600 °C, and monolayer graphite on Ni(111) was shown to have an arrangement whereby one carbon atom in a unit cell of the graphite overlayer is located at the on-top site of the topmost Ni atoms, while another carbon atom exists at the *fcc* hollow site [2.22]. Carbon has been shown to segregate on the surface of Ru(0001) as monolayer graphene [2.23], when annealed at 1400 K. *STM* reveals a (11×11) structure with good rotational alignment and structural perfection, a well-defined periodicity of ≈ 30 Å, and large domain sizes exceeding 100 μm . Graphene has also been grown by thermal decomposition of benzene on Ir(111) [2.24].

At present, the two predominant metallic substrates for *CVD* graphene growth are Ni and Cu. Large-size (cm^2) films of monolayer and few-layer graphene have been grown on Ni [2.25], with monolayer regions as large as 20 μm in size. Cu does even better, and predominantly monolayer graphene covering many cm^2 is grown in various laboratories using methane *CVD* [2.26]. The solubility of C in Cu appears to make the process self-limiting, and at most 5% of the surface is covered by small islands of bilayer graphene. Most importantly, methods have been developed to detach these films from the metallic substrate and transfer them intact onto dielectric substrate (Fig. 2.4), where they can be lithographically patterned and processed for electronic or optical applications [2.25]. In another variation, graphene is grown on a thin copper film on

arbitrary substrates, and the Cu dewets and evaporates during the growth process itself, leaving behind the graphene film intact on the substrate [2.27]. The first truly large-area production of graphene has recently been reported using a continuous *CVD* deposition and transfer process [2.28].

In general, for substrates with small lattice mismatch ($< 1\%$) such as Co(0001) and Ni(111), commensurate superstructures are formed, while substrates with larger mismatches such as Pt(111), Ir(111), and Ru(0001) yield incommensurate moiré superstructures. The first graphene monolayer on the metal surface has strong interaction with the substrate, and the spacing between the two is much shorter than between two layers of graphite (3.35 Å). For the case of Ru it is 1.45 Å, and for Ni it is 2.11 Å.

2.1.3 Decomposition of Carbides

The second substrate-supported route for graphene production involves thermal decomposition of surface layers of carbides such as SiC. About 250 different crystal structure of SiC are known, but α -SiC is the most commonly encountered polymorph and, until recently, the primary focus of epitaxial graphene growth. α -SiC has a hexagonal crystal structure, similar to wurtzite. The (0001) (Si) and (000 $\bar{1}$) (C) faces of 6H-(α -SiC) [2.29–31] and 4C-(α -SiC) [2.32] have been shown suitable for the growth of epitaxial graphene.

6H-(α -SiC) is first cleaned for 20 min at 850 °C under a Si flux to prevent Si sublimation during the cleaning step. At higher annealing temperatures in ultrahigh vacuum (*UHV*), the surface of SiC undergoes various reconstructions, until the graphitization temperature when the surface graphene layers form. The Si surface of the hexagonal SiC undergoes the following reconstructions: 3×3 at 850 °C under Si flux, $\sqrt{3}\times\sqrt{3}R30^\circ$ below 1000 °C, $6\sqrt{3}\times 6\sqrt{3}R30^\circ$ (6R3) at 1150 °C, and graphitization at 1350 °C. On this face, the C atoms are in epitaxy with the SiC underneath after graphitization. The surface is passivated by the first C layer, the interface extends to two C layers, and subsequent C layers are decoupled from the substrate and exhibit the properties of graphene. Graphitization occurs at 1150 °C on the C face of the hexagonal SiC, and the C layer occurs on a SiC 2×2 native reconstruction. This reconstruction saturates the dangling bond states, so that the first C layer already exhibits graphene properties. However, this C layer is no longer epitaxial with the underlying SiC, so the long-range order of the SiC substrate no longer imposes itself upon the

Fig. 2.4a-d Graphene films transferred onto (a) a SiO₂/Si substrate and (b) a glass plate. (c) Scanning electron micrograph (SEM) image of graphene transferred onto SiO₂/Si (285 nm-thick oxide layer), showing wrinkles as well as two- and three-layer regions. (d) Optical microscope image of the same regions as in (c) (after [2.26])

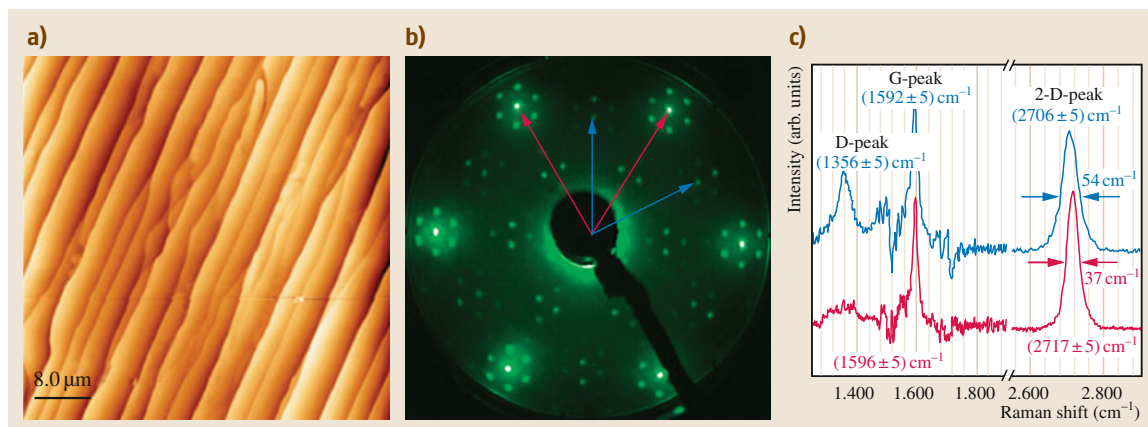

Fig. 2.5 (a) AFM image of graphene on 6H-SiC(0001) formed by annealing in Ar ($p = 900$ mbar, $T = 1650$ °C). (b) Low energy electron diffraction (LEED) pattern at 74 eV showing the diffraction spots due to the SiC(0001) substrate (blue arrows) and the graphene lattice (red arrows). The extra spots are due to the $(6\sqrt{3} \times 6\sqrt{3})$ interface layer. (c) Comparison of Raman spectra of Ar-grown (red) and UHV-grown (blue) epitaxial graphene (after [2.33])

C layer. Therefore, it has not been possible to accomplish both long-range ordering as well as decoupling from the surface simultaneously using 6H-(α -SiC). Epitaxial graphene has also been grown on SiC(0001) in Ar atmosphere [2.33], at close to atmospheric pressure and a significantly higher annealing temperature of 1650 °C, resulting in morphologically and electronically superior graphene compared with vacuum annealing (Fig. 2.5).

Perhaps the greatest limitation of SiC as a substrate for graphene growth is cost. α -SiC wafers are relatively expensive, at about USD 300 for a 50 mm wafer. Cubic 3C-SiC (β -SiC), however, can be grown directly on the surface of Si wafers of 300 mm and larger, and is therefore a more commercially viable substrate. It was believed that, due to its cubic struc-

ture, β -SiC would be unsuitable for graphene growth. However, recently scientists have succeeded in growing graphene on the Si-rich (100) surface of β -SiC by a series of annealing cycles with temperature increasing from 1200 to 1550 K [2.34]. They found that the strong lattice mismatch between graphene and underlying SiC results in very weak coupling similar to the (000 $\bar{1}$) C face of α -SiC. However, it was found that graphene growth on β -SiC was guided along the [110] crystallographic direction despite the lattice mismatch, raising hopes that both substrate-graphene decoupling as well as substrate-guided large domain size might be simultaneously achievable after further process optimization and characterization of graphene on β -SiC.

Ribbons of graphene, a few nanometers wide, develop an electronic bandgap due to confinement effects, which is absent in larger dimensions of graphene, which is a zero-bandgap semimetal. The importance and methods of inducing a bandgap in graphene are discussed later. Here, we briefly discuss how SiC decomposition can be used to grow graphene nanoribbons [2.35]. It is known that the (0001) face of both 6H and 4C α -SiC with vicinal miscuts towards (1 $\bar{1}$ 00) displays bunching of parallel steps into (1 $\bar{1}$ 0*n*) nanofacets up to 4–5 unit cells in height and oriented at an angle of $\approx 25^\circ$ to the basal plane. The α -SiC (000 $\bar{1}$) face generally does not show preferential orientation for nanofacets, but step-bunched (1 $\bar{1}$ 0*n*) nanofacets can be induced by suitable pretreatment. It has also been observed that graphene grown on the (0001) and (000 $\bar{1}$) faces of α -SiC are continuous over these steps. Controlled facets can be achieved by conventional photolithography and microfabrication. Few-layer graphene is shown to grow selectively on these facets. Facets of other crystallographic orientations are possible, and it is expected that the graphene quality, properties, and growth mechanism will depend significantly on the crystallographic surface. However, these preliminary results indicate that, with further research and optimization, the ideal facets and growth conditions might be determined for large-scale controlled growth of graphene nanoribbons.

Interestingly, there was significant research into the growth and characterization of graphene on other metal carbides [2.36–38], such as TiC, TaC, and HfC, as early as the 1980s. Then, it was referred to as *monolayer graphite*. Graphene has been grown on the (100) and (111) faces of these carbides by heating them to 1700 K in UHV. As with SiC, graphene nanoribbons as narrow as 1.3 nm with well-defined edge structure have been grown, for instance, on TiC (755) surface [2.39]. In all these cases, a significant degree of hybridization between the graphene π -electrons and the electronic bands of the substrate carbide was reported, similar to some of the crystallographic faces of SiC. Despite the revelation that the graphene is significantly decoupled from certain other SiC faces, similar exploration into other metallic carbides remains pending.

2.1.4 Exfoliation by a Solvent

Exfoliation of graphene from graphite involves overcoming the interlayer van der Waals bonds. This is the same interaction in play between individual CNTs in a bundle. Just as ultrasonication in a solvent has been used to overcome this weak force and separate

and disperse individual CNTs from a bundle, it has also been used to individualize graphene layers from graphite. This process can be facilitated if the interlayer attraction can be compromised by intercalates. The resultant flakes of graphene in a solvent can be stabilized to prevent aggregation, and separated into fractions which are enriched in particular graphene thicknesses.

Graphite Intercalation Compounds

Due to the nature of hybridization of carbon atoms in graphite, it is capable of reactivity involving incorporation of atoms, ions, or molecules in its lattice while leaving its basic structure unchanged. Such graphite intercalation compounds (GIC) [2.40] may be broadly classified into those with homopolar bonding and polar bonding. Graphite oxide (GO) and graphite fluoride (GF) are examples of homopolar bonding, while potassium-, rhodium- and cesium-graphite are examples of polar bonding. GICs were well studied as early as the 1950s and are a staple of chemistry textbooks. Here, we restrict our discussion to exfoliation of GICs, in particular graphite oxide, and its reduction to graphene, which has been achieved with varying degrees of success. A family of GICs with interhalogen compounds offers control over the stage of intercalation and subsequently the layer distribution in the resultant graphene.

Graphite can be oxidized to GO in various ways. In the *modified Staudenmaier method* [2.41] a mixture of 97% sulfuric acid and fuming nitric acid is cooled down to 5 °C in an ice bath, graphite in flake or powder form is added, followed by repeated additions of potassium perchlorate every hour over a period of 3 days. The resulting solution, sometimes referred to as graphitic acid, is filtered and washed until the pH of the filtrate reaches 5 or more. The *Brodie method* [2.41] is identical, except that only nitric acid is used, and the potassium perchlorate is added every hour for 3 h. In the *Hummers method* [2.42, 43], graphite is oxidized in a mixture of concentrated sulfuric acid, sodium nitrate, and potassium permanganate at 45 °C for 2 h. At this stage, the material is often referred to as *expandable graphite*, reasons for which are explained in the next section. In the *electrochemical method* [2.41], a graphite sheet electrode is anodically polarized in perchloric acid with a platinum wire as counterelectrode. When dried, the above methods result in a powder consisting of graphite oxide flakes. Graphite fluoride has also been used as a starting point for graphene dispersions. Graphite can be fluorinated under fluo-

Fig. 2.6 (a) HOPG before (top) and after (bottom) oxidation and expansion (after [2.45]). (b) Deoxygenation of exfoliated GO under alkaline conditions (after [2.46]). (c) AFM image of exfoliated monolayer graphene oxide sheets (after [2.47])

rine pressure of 200 mmHg, in a temperature range of 375–640 °C [2.44].

Interhalogen compounds such as IBr and ICl also form GICs, offering control over the stage of intercalation. Stage I GIC refers to intercalation of every layer of graphite, while stage II GICs only have every second layer of graphite intercalated, and stage III GICs have every third layer intercalated, etc. As discussed in subsequent sections, bilayer and trilayer graphene are electronically distinct from monolayer graphene and in certain instances, such as semiconductor electronics, might prove superior to monolayer graphene. Exfoliation of graphene from stage II and stage III GICs has been shown to yield solutions of predominantly bilayer and trilayer graphene [2.48], and is currently the only large-scale route available to synthesize these multi-layer graphenes.

From GIC to Graphene

Usually, the next step involves expansion of intercalated graphite by decomposing and expelling the intercalate. Rapid annealing of expandable graphite to 1050 °C generates high-pressure gaseous decomposition products which force the individual layers apart. This results in a ≈ 100 -fold expansion in the interlayer spacing in graphite, and the material is now referred to as expanded graphite (Fig. 2.6a) [2.45, 47]. Similarly, interhalogen GICs can be expanded by expelling the entrapped intercalants.

Expanded graphite or graphite oxide is dispersed in a solvent by ultrasonication, resulting in graphene or GO solutions, respectively. In the case of GO, the predominant product in solution is monolayer GO, while stage II and III GICs of interhalogen compounds yield solutions of predominantly bilayer and trilayer graphenes. Alternatively, GO can be intercalated and exfoliated, for instance, by tributylammonium cations [2.49]. The phenol, carbonyl, and epoxy groups

resulting from the oxidation of graphite ensured colloidal stability in polar solvents [2.50]. Polymers, surfactants, DNA, etc. can be used to provide additional stabilization of the GO flakes in colloidal suspension. Edge-selective diazonium functionalization [2.51] has also been demonstrated as a way to stabilize high-concentration graphene solutions without the stabilizing agents perturbing the bulk structure of the graphene sheets.

Exfoliated GO can be subsequently reduced to yield reduced GO. It cannot be referred to as graphene at this stage due to the incomplete nature of the reduction process. One route involves reduction in water with hydrazine hydrate [2.52, 53] or dimethylhydrazine [2.54]. A reduced GO suspension can also be obtained by heating the exfoliated GO suspension under strongly alkaline conditions by addition of NaOH at 50–90 °C (Fig. 2.6b) [2.46]. Alternately, the flakes can be deposited in a substrate and reduced by hydrazine vapors or hydrogen plasma [2.55]. All these methods result in the formation of unsaturated and conjugated carbon atoms, which results in electrical conductivity and Raman signatures intermediate between those of GO and pristine graphene.

GF can be reacted with *n*-butyl and *n*-hexyl lithium reagents in hexane at 0 °C. The alkyl lithium reagent replaces the fluorine functionalization during this process. The product can then be dispersed in ethanol by sonication. The alkyl functionalization, followed by a subsequent annealing step, partially restores the pristine graphene structure similar to reduced GO [2.56]. A one-step electrochemical approach has been demonstrated to form ionic liquid functionalized graphite sheets, which are then exfoliated into functionalized graphene dispersed in polar aprotic solvents [2.57].

It is also possible to exfoliate noncovalent GICs to yield graphene flakes that do not suffer the disadvantage

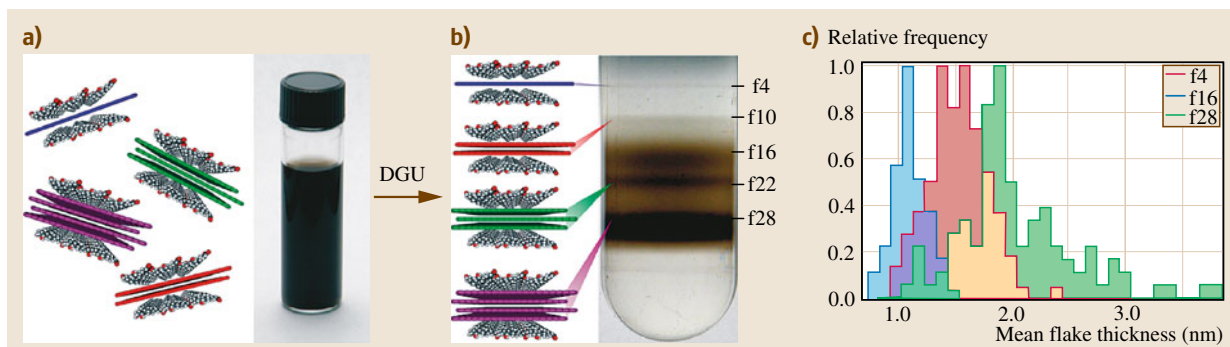

Fig. 2.7 (a) Schematic illustration of ordered sodium cholate encapsulation of graphene sheets and a photograph of an unsorted aqueous graphene suspension with graphene loading of ≈ 0.1 mg/ml. (b) Photograph of a centrifuge tube following DGU marked with the main bands of monodisperse graphene. of high defect density; for instance, alkali-metal GICs have been shown to readily and spontaneously exfoliate in *N*-methyl-pyrrolidone (NMP), yielding a stable solution of negatively charged graphene sheets. Graphene can also be noncovalently functionalized and exfoliated with 1-pyrenecarboxylic acid by continuous sonication in water [2.58]. Interhalogen compounds do not covalently functionalize the graphite upon intercalation, and therefore the resultant solution is one of pure graphene, without any need for further reduction or reconversion.

Exfoliation Without Intercalation

In an effort to avoid disruption to the desirable structure and properties of graphene, efforts have been undertaken to directly exfoliate and disperse graphite in a solvent by ultrasonication, as has been successfully demonstrated for debundling CNTs. Systematic study has been undertaken in the case of CNTs to explore their solubility in various solvents without the assistance of stabilizing agents such as surfactants. It has emerged that certain solvents such as *N*-methyl-pyrrolidone and *N,N*-dimethylamide (DMA) are ideally suited to dissolve CNTs in significant concentration [2.60]. Dissolution of CNTs in aqueous media is only possible using stabilizing surfactants; however, these solutions have emerged as the premier option among researchers, since the adsorbed surfactants can be easily desorbed or disintegrated if and when required.

Sieved graphite powder was dispersed in NMP by bath sonication. The macroscopic particles and aggregates were sedimented by mild centrifugation (500–2000 rpm), resulting in a homogeneous dark dispersion which was found to contain a high fraction

of monolayer and few-layer graphene flakes [2.61]. Other solvents such as DMA, γ -butyrolactone, and 1,3-dimethyl-2-imidazolidinone yield similar results. The procedure has been adopted successfully for using water as solvent, in the presence of sodium dodecylbenzene sulfonate or sodium cholate as stabilizing surfactant [2.62]. The predominant drawback of this process lies in the fact that the sonication breaks up the graphene into particularly small fragments, with the monolayer flakes having lateral dimensions of, on average, 100 nm. This is similar to the case of CNTs, where sonication appears to cut them down to ≈ 200 nm [2.63]. The aqueous graphene dispersion can now be processed by density-gradient ultracentrifugation (DGU) using iodixanol as density medium to yield fractions enriched in particular graphene thicknesses (Fig. 2.7) [2.59]. Highly enriched solutions of monolayer and bilayer graphene with the above size limitation are now available for research purposes from commercial sources such as Nanointegris, but not yet in industrial quantity.

Single- and few-layer graphene sheets with sizes up to 0.1 mm have been fabricated by quenching hot graphite in ammonium hydrogen carbonate aqueous solution [2.64]. Few-layer graphene has also been produced by immersing and intercalating graphite in supercritical CO₂ for 30 min followed by rapidly depressurizing the supercritical fluid to expand and exfoliate the graphite [2.65]. The expanding CO₂ gas containing the graphene flakes was collected directly in an aqueous solution containing stabilizing surfactant to avoid aggregation. Other supercritical fluids, such as ethanol, NMP, and DMF, can also be used to exfoliate graphite into graphene [2.66].

2.1.5 Synthetic Production Route

If the reduction of bulk graphite into graphene is viewed as a top-down approach, then the chemical synthesis of graphene from smaller aromatic hydrocarbons will constitute the bottom-up approach. If graphene is regarded as a polycyclic aromatic hydrocarbon (PAH), one of the largest of these synthesized involves 222 carbon atoms or 37 benzene units in a hexagonal structure, 3 nm in diameter [2.72], from an oligophenylene precursor which was planarized by oxidative cyclohydrogenation. These structures have also shown a high tendency to self-assemble on surfaces [2.73] and could potentially act as precursors for larger synthetic graphene.

2.1.6 Graphene Nanoribbon (GNR)

The techniques described here have been suitably modified and developed with particular focus on forming very narrow ribbons of graphene with widths of tens of nanometers and with well-defined edge structure and orientation (Fig. 2.8). This is of particular importance in electronic applications, since such nanoribbons of graphene are one of the means to engineer an electronic bandgap in otherwise gapless graphene, as discussed in detail in Sect. 2.3.6. Once graphene flakes have been deposited onto a substrate, nanoribbons can be fabricated on it using standard and nonconventional lithography and etching processes, such as electron-beam lithography [2.74] and nanowire lithography [2.75], respectively.

Nickel [2.76] and silver [2.77] nanoparticles have been shown to act as a *knife* for cutting patterns in surface graphite layers of HOPG. The cutting proceeds via catalytic hydrogenation of the graphene lattice, and

preferentially along crystallographic directions. The particles can become deflected into proceeding along a different direction if they come within close proximity of each other, of defects in the graphene lattice, or of previously formed cuts. The result is a complex pattern of cuts which border various well-defined shapes of the surface graphene layers, including instances where two parallel cuts result in a narrow ribbon between them. These shapes can be transferred onto arbitrary substrates using the mechanical exfoliation methods described earlier [2.67]. The graphene can also be cut into ribbons after they have been transferred onto any arbitrary substrate [2.78].

Expanded graphite was dispersed in a 1,2-dichloroethane (DCE) solution containing a polymer poly(*m*-phenylenevinylene-co-2,5-dioctoxy-*p*-phenylenevinylene) (PmPV) by sonication for 30 min followed by centrifugation to remove larger aggregates. The supernatant after sonication was shown to contain an appreciable fraction of graphene nanoribbons and related morphologies such as ribbons with kinks, bends, and nonparallel sides [2.71]. The exact mechanism or variation to the liquid-phase exfoliation procedures described earlier that results in the significant yield of nanoribbons in this case is not clearly understood.

Graphene nanoribbons, 8–12 nm in length and 2–3 nm width, have also been synthesized by surface-assisted coupling of molecular precursors into linear polyphenylenes and their subsequent cyclohydrogenation [2.68].

CNTs have been described as rolled-up graphene sheets, and now graphene nanoribbons have been made from unraveling CNTs. Oxidized nanoribbons were obtained by suspending CNTs in concentrated sulfuric acid followed by treatment with 500 wt.% KMnO₄ for

1 h at 22 °C and 1 h at 55–70 °C. The process, described as CNT unzipping, could occur as a linear longitudinal cut or in a spiral manner depending on the chirality of the CNT [2.70]. CNTs have also been converted to GNR by controlled plasma etching of CNTs that are partially embedded in a polymer film [2.69].

2.1.7 Derivatives of Graphene

Graphane, a fully saturated hydrocarbon derived from graphene, with formula CH , was predicted to be stable based on first-principles total-energy calculations [2.79]. Experimentally, it was later shown that graphene can be hydrogenated and converted to graphane using a low-pressure (0.1 mbar) hydrogen-argon mixture (10% H_2) with direct-current (DC) plasma for 2 h [2.80]. The hydrogenation is stable but

reversible, and the graphane can be reconverted to graphene by annealing at 450 °C in Ar atmosphere for 24 h. The reconverted graphene, however, contains remnant defects just as vacancies and oxygenated or hydrogenated carbon atoms. In the case of substrate-supported graphene, only one side is hydrogenated, while both sides can be hydrogenated in the case of suspended graphene.

Graphene can also be fluorinated with xenon difluoride. When one side is exposed, F coverage saturates at 25% (C_4F), whereas fluorination of both sides results in perfluorographene [2.81] and fluorographene [2.82], which are the nonstoichiometric and stoichiometric variations. Nonstoichiometric and multilayered fluorographene can also be exfoliated from graphite fluoride [2.56, 83]. Hydrazine treatment has been shown to reverse the fluorination.

2.2 Properties

While its very existence as a freestanding two-dimensional material is a feather in graphene's cap, it is the properties of graphene that make it the truly exceptional material that has stoked feverish research in this field. The individual properties of pristine graphene are discussed first, while the properties of graphene derivatives such as GO, graphane, and fluorographene are discussed in the final section.

2.2.1 Structure and Physical Properties

Graphene shares most of its structure and physical properties with graphite, its parent material. The carbon atoms are arranged in a two-dimensional hexagonal lattice (Fig. 2.9b), which can also be constructed as two interpenetrating triangular sublattices, which takes particular significance in bilayer and other multilayer graphenes. The carbon atoms are sp^2 hybridized, and the in-plane carbon-carbon bond length is $a = 1.42 \text{ \AA}$. The remaining p-orbital is oriented perpendicular to the plane of carbon atoms and delocalizes to form the π (valence) and π^* (conduction) electronic bands which are discussed in detail in Sect. 2.2.3. The carbon layers are usually stacked in an ABAB (Bernal) stacking; however, in certain few-layer graphenes such as that grown by CVD, the layers are rotated with respect to this standard arrangement. The interplane spacing is 3.45 \AA . A staggered ABCABC (rhombohedral) arrangement is also possible, but has not

been realized by any of the graphene production routes.

Two-dimensional structures such as graphene have been postulated to be intrinsically unstable, and according to the Mermin-Wagner theorem [2.84], long-wavelength fluctuations destroy the long-range order of 2-D crystals. Even 2-D crystals embedded in 3-D space have a tendency to crumple. The puzzling stability of suspended 2-D graphene sheets has been attributed to intrinsic microscopic undulations in which the surface normal varies by several degrees and the out-of-plane deformation reaches 1 nm [2.9, 85]. This observation by TEM is discussed further in Sect. 2.3.2 and also conforms to atomistic Monte Carlo simulations. Similar corrugation has also been reported on graphene supported on SiO_2 substrates, where it is a superposition of intrinsic rippling as well as extrinsic undulations imposed by the substrate surface morphology [2.86]. Periodic ripples have also been observed on weakly coupled graphene monolayers on substrates such as Ru(0001) [2.87]. Corrugations in substrate-supported graphene are primarily observed by STM and are discussed further in Sect. 2.3.3. In addition to ripples, substrate-supported graphene also exhibits ubiquitous wrinkles which could be several nanometers in width. Scrolling has been occasionally observed at the edges of graphene flakes, both suspended [2.88] and substrate supported [2.89], and this appears to rely on the fabrication method. Scrolling occurs when graphene is

Fig. 2.9 (a) SEM of graphene suspended over a macroscopic hole of a Cu TEM grid (after [2.90]). (b) Structure of graphene (after [2.92])

subjected to liquid-phase processing during microfabrication, while its solid-phase or gas-phase processing appears to avoid this [2.90], and it is possible to obtain large free-standing sheets of monolayer graphene (Fig. 2.9a). The ripples in graphene also result in perturbations in the electronic structure, and many electronic and chemical properties of graphene have been attributed to these ripples, rather than being intrinsic to graphene. However, it has been shown that graphene deposited on atomically flat terraces of cleaved mica surfaces is flat down to the atomic scale [2.91]. The height variation observed by AFM was less than 25 pm, and such *ultraflat* graphene is expected to permit exploration of various intrinsic physical and chemical properties of graphene.

2.2.2 Mechanical Properties

Carbon materials have made it a habit of setting records for their intrinsic mechanical properties. Diamond is the hardest known natural material, and is assigned a grade of 10 (highest) on the Mohs scale of mineral hardness [2.93]. Similarly, the record for tensile strength has been held by CNTs; a Young's modulus of 1 TPa and tensile strength of 150 GPa coupled with elongation to failure as high as 20% have been experimentally reported [2.94].

The earliest experimental indication for the extraordinary stiffness of graphene was the observation that graphene *beams* supported on only one end do not scroll or fold, quite unlike the papery or cloth-like appearance of graphene. If the effective thickness of monolayer graphene is estimated to be 0.23 Å from elastic theory, a bending rigidity of 1.1 eV [2.85], and a Young's

modulus of $22 \text{ eV}/\text{\AA}^2$ from the elastic modulus of bulk graphite [2.95], the lengths of unsupported graphene observed in TEM samples have been 10^6 times larger than its effective thickness. Suspended graphene can gain additional thickness from large-scale corrugations by a factor of $(H/a)^2$, where H is the characteristic height of the corrugations. In addition to supporting its own weight, suspended graphene has been shown to support significant extra load such as copper nanoparticles [2.90], as well as surviving accidental shocks such as during handling.

Direct measurements of the elastic properties of graphene have been conducted by nanoindentation of suspended graphene layers in an AFM [2.96, 97]. Details of the measurement technique are found in Sect. 2.3.3. Measurements conducted on few-layer graphene of less than 8 nm thickness yielded spring constants of 1–5 N/m. A Young's modulus of 0.5 TPa was extracted by fitting the data to a model for doubly clamped beams under tension. For measurements on monolayer graphene, the force–displacement characteristics yield second- and third-order elastic stiffness of 340 and –690 N/m, respectively. The breaking strength was found to be 42 N/m, which represents the intrinsic strength of a defect-free sheet. This corresponds to Young's modulus $E = 1.0 \text{ TPa}$, third-order elastic stiffness of 2.0 TPa, and intrinsic strength of 130 GPa. These figures mean that graphene is the strongest material ever measured.

Nonlinear finite elasticity theory for graphene resonators for both electrostatic and electrodynamic cases has been developed and agrees well with experiments on graphene resonators [2.98]. The dynamic response of clamped graphene resonators resembles that of coupled

Fig. 2.10 (a) Schematic of graphene resonator, with electrostatic actuation and electrical readout. (b) SEM image of such a resonator. (c) The graphene resonance (I) at 65 MHz. Resonances of metal beams (II) are also visible below 25 MHz. *Inset*: the graphene resonance at low driving power, and Lorentzian fit (red line) with $Q = 125$ (after [2.102])

Duffing-type resonators. Similarly, a continuum plate model for the vibration of multilayered graphene sheets, including the van der Waals (vdW) interaction between the layers, suggests that the lowest natural frequencies are identical for various numbers of layered graphenes. Higher resonance frequencies, however, depend on the vdW interaction and are different for different layered graphenes [2.99]. In general, natural resonance frequencies in the THz regime are expected for graphene resonators, due to the combination of their extreme thinness and extraordinary stiffness. Experimentally, the mechanical vibrations in electrostatically actuated graphene resonators have been imaged by a special modification of atomic force microscopy [2.100]. Resonance frequencies in the tens of MHz have been recorded in graphene resonators (Fig. 2.10), with quality factors as high as 4000 at room temperature [2.101] and 10 000 at 5 K [2.102].

2.2.3 Electronic Properties

Electronically, monolayer, bilayer, and trilayer graphene are electronically distinct materials. Beyond three layers, graphene's electronic properties tend towards those of bulk graphite. In certain aspects, graphene of up to 10 layers might exhibit deviation in electronic properties from bulk graphite and could be referred to as graphene, but beyond 10 layers all graphenes are indistinguishable from graphite.

Monolayer Graphene

The electronic structure of graphene was first described in 1946 [2.103], as a theoretical building block to de-

scribe graphite. The valence and conduction bands of graphene are conical valleys that touch at the high-symmetry K and K' points of the Brillouin zone. Near these points, the energy varies linearly with the magnitude of momentum, i.e., follows a linear dispersion relation. In neutral graphene, this point of intersection coincides with the charge neutrality point, and is referred to as the Dirac point.

In every other material known to condensed matter physicists, the electrons behave as and can be described by the Schrödinger equation. In graphene, on the other hand, electrons have been shown to behave as relativistic particles, and should be described by the Dirac equation [2.104–106]. The interaction of electrons with the periodic potential of the graphene hexagonal lattice results in quasiparticles, which can be viewed as electrons devoid of their rest mass m_0 and therefore called massless Dirac fermions. The linear energy dispersion means that the speed of electrons in graphene is a constant, independent of momentum, as in the case of the speed of photons. The velocity of electrons in graphene is $\approx 10^6$ m/s, about 300 times slower than the speed of light (photons).

The electronic states near the Dirac point are composed of states belonging to the two graphene sublattices, and as a result the quasiparticles possess pseudospin, similar to the electron's spin [2.107, 108]. As a result, these Dirac fermions are said to be chiral. Another relativistic feature of these quasiparticles is the Klein paradox [2.107], wherein they tunnel through a potential barrier of any height and width with a transmission probability of 1 or without a reflected component. As a result, electrons in graphene

Fig. 2.11a–c Electronic structure of (a) monolayer, (b) symmetric bilayer, and (c) asymmetric bilayer of graphene (after [2.109])

can propagate over (relatively) vast distances of the order of microns through the graphene lattice, even in the presence of lattice defects or other external perturbing potentials [2.4].

Bilayer Graphene

If the hexagonal atomic structure of graphene is composed of nonidentical elements, such as in boron nitride, the lateral in-plane symmetry is broken and a large bandgap is formed between the π and π^* states. This is the case in bilayer graphene, where the AB (Bernal) stacking between the two graphene renders the two carbon atoms inequivalent and results in two graphene sublattices. As a result, the unit cell of bilayer graphene contains four atoms, and two additional bands result (π and π^* states). If the inversion symmetry between the two layers is broken, then an energy gap between the low-energy valence and conduction bands forms at the Dirac point (Fig. 2.11).

The first experimental demonstration of this effect was performed on bilayer graphene synthesized on SiC (6H, (0001) orientation) [2.109]. The as-grown graphene is n-doped due to the depletion of the substrate's dopant carriers. At low temperature, the SiC dopant electrons are frozen out and the substrate acts as a nearly perfect insulator while the excess electrons in graphene retain their high mobility. In this case, the symmetry of the bilayers is broken by the dipole field created between the depletion layer of the SiC and the accumulation of charge on the graphene layer next to the interface. Further n-type doping can be introduced by deposition of potassium atoms onto the vacuum side, which donate their lone valence electrons to the graphene layer, forming another dipole. The binding energy–momentum dispersion relation of π , π^* , and σ states along high-symmetry directions was measured by

angle-resolved photoemission spectroscopy (ARPES) (Fig. 2.12). The relative potential of the top and bottom graphene layers is varied by changing the doping level by potassium adsorption. An apparent gap at the K point appears in the as-prepared graphene, disappearing and reappearing with increasing level of K doping.

The electronic gap in bilayer graphene can thus be controlled by applying an external transverse electric field, such as by a gate bias, making it the only known semiconductor material with a tunable energy gap. Using a tight-binding model, the value of the gap was extracted as a function of electron density, showing that it can be tuned to values larger than 0.2 eV, using fields of ≈ 1 V/m.

The two key semiconductor parameters, the electronic bandgap and carrier doping concentration, can also be independently tuned by using a dual-gate configuration. Reliable determination of the bilayer bandgap has been carried out in such a configuration using infrared microscopy [2.110]. Figure 2.13 shows the gate-modulated bilayer absorption spectra at the charge neutrality point. The two features present in the spectra, a peak below 300 meV and a dip around 400 meV, arise from different optical transitions between the bilayer electronic bands. Transition I shows pronounced gate tunability up to 250 meV at 3 V/nm, since it accounts for the bandgap-induced spectral response.

By examining the electronic band structure of graphene around the K point within a tight-binding approach, it has been shown that a single graphene layer is a zero-gap semiconductor with a linear Dirac-like spectrum around the Fermi energy, while graphite shows semimetallic behavior with band overlap of about 41 meV. Bilayer graphene has a parabolic band structure around the Fermi energy and is a semimetal like graphite; however, the band overlap is only 0.16 meV.

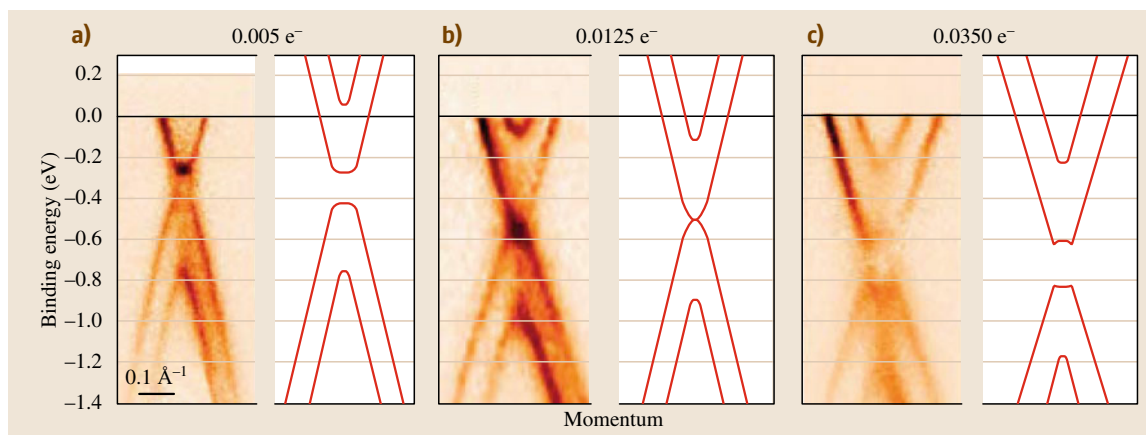

Fig. 2.12a–c Evolution of gap closing and reopening by changing the doping level by potassium adsorption. Experimental and theoretical bands (*solid lines*) for **(a)** as-prepared graphene bilayers and **b,c** with progressive adsorption of potassium are shown. The number of doping electrons per unit cell, estimated from the relative size of the Fermi surface, is indicated at the top of each panel (after [2.109])

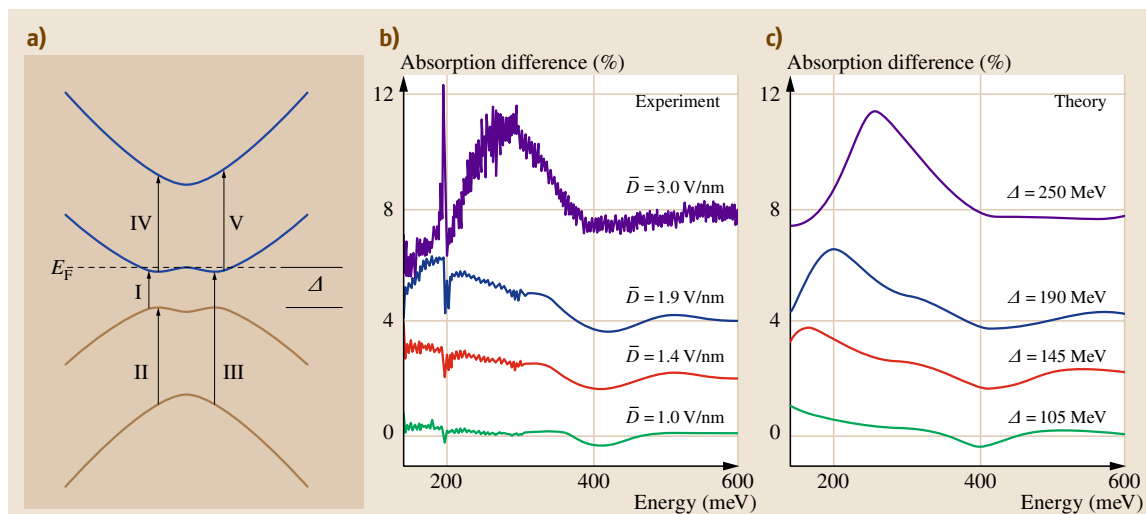

Fig. 2.13a–c Infrared spectroscopy to probe bilayer energy gap opening at strong electrical gating. **(a)** Allowed optical transitions between different subbands of a graphene bilayers. **(b)** Gate-induced absorption spectra at the charge neutrality point for different applied displacement fields \bar{D} . Curves are offset from zero for clarity. **(c)** Theoretical prediction of gate-induced absorption spectra based on a tight-binding model where the bandgap value is taken as an adjustable parameter. The fit provides an accurate determination of the gate-tunable bandgap at strong electrical gating (after [2.110])

This overlap increases with the number of graphene layers, and for 11 or more layers it is smaller than 10%.

Superconductivity

Andreev reflection at a metal–superconductor junction involving graphene is fundamentally different from normal metals [2.111]. In weakly doped graphene,

electron–hole conversion involves electrons from the conduction band being converted into a hole from the valence band. This interband conversion is associated with specular reflection instead of the retroreflection found in normal metals where electron–hole conversion occurs within the conduction band (Fig. 2.14). The Josephson effect has also been experimentally stud-

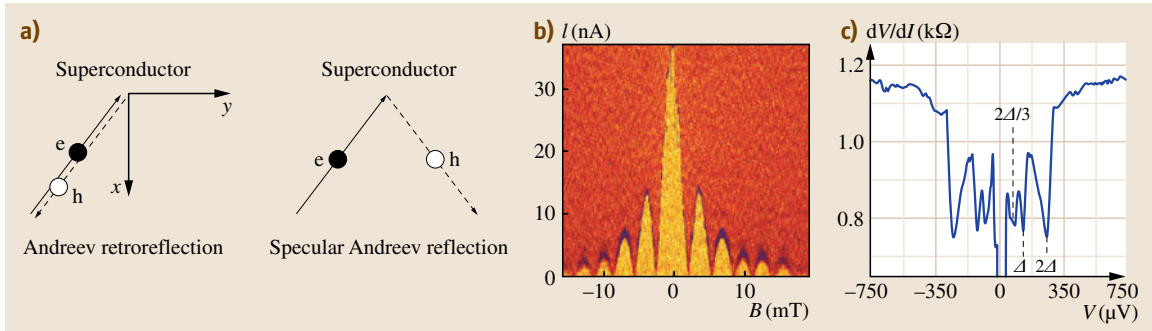

Fig. 2.14 (a) Andreev retroreflection (*left*) at the interface between a normal metal and a superconductor, and specular Andreev reflection (*right*) at the interface between undoped graphene and a superconductor. Arrows indicate the direction of the velocity, and solid or dashed lines distinguish whether the particle is a negatively charged electron (e) or a positively charged hole (h) (after [2.111]). (b) Josephson effect in graphene: $dV/dI(I, B)$ at $T = 30$ mK (yellow-orange is zero, that is, the supercurrent region, and red corresponds to finite dV/dI) (after [2.112]). (c) dV/dI versus V , showing multiple Andreev reflection dips below the superconducting energy gap. The dips in dV/dI occur at values of $V = 2\Delta/en$, where n is an integer number (after [2.112])

ied in macroscopic junctions consisting of a graphene layer contacted by two closely spaced superconducting electrodes (SGS) [2.112, 113]. A supercurrent is observed, which can be carried either by electrons in the conduction band or by holes in the valance band, as determined by the gate voltage. A finite supercurrent is also observed at zero charge density at the charge neutrality point, indicating phase-coherent electronic transport at the Dirac point. The diffusive junction model has been shown to yield quantitative agreement with experiments [2.114], while a ballistic SGS model is inconsistent with the data. This is attributed to potential fluctuations in graphene due to the influence of the substrate as well as metallic leads. Crossed Andreev reflection in graphene–superconductor–graphene junctions [2.115] and Andreev reflection in graphene nanoribbons [2.116] have been theoretically investigated, but experimental confirmation remains pending.

2.2.4 Optical Properties

Successful exfoliation of monolayer graphene depends on the recognition of the optical properties of graphene more than the exfoliation procedure [2.7]. The choice of 300 nm-thick SiO_2 on Si substrate allowed optical identification of the exfoliated monolayer graphene, which would otherwise have been invisible and not practically detectable; for instance, only flakes thicker than ten layers can be found in white light on top of 200 nm SiO_2 , which also marks the commonly accepted tran-

sition from graphene to bulk graphite. The contrast of a graphene flake depends not only on the SiO_2 thickness but also on the wavelength λ of light used. Figure 2.15 summarizes the expected contrast as a function of SiO_2 thickness as well as wavelength of monochromatic illumination, derived using Fresnel theory. It was also inferred that the complex refractive index of graphene is the same as that of bulk graphite, $n = 2.6 - 1.3i$, which is independent of λ . This can be explained by the fact that the optical response of graphite with the electric field parallel to graphene planes is dominated by the in-plane electromagnetic response. Since changes in the light intensity due to graphene are relatively minor, the observed contrast can be used to determine the number of graphene layers.

The absorbance of light by monolayer and bilayer graphene has been measured to be 2.3 and 4.6%, respectively, in the visual regime (450–750 nm), and this extends linearity up to five layers. The optical transparency of noninteracting graphene is solely determined by the fine structure constant of quantum electrodynamics ($\alpha = e^2/\hbar c = 1/137$), which describes the coupling between light and relativistic electrons [2.117, 118]. This is because, as discussed in the previous section, the electrons in graphene behave as relativistic Dirac particles and electron–electron Coulomb interactions can be neglected. The high-frequency (dynamic) conductivity G for Dirac fermions in graphene is a universal constant equal to $e^2/4\hbar$. The universal G implies that observable quantities such as graphene’s optical transmittance T and reflectance R are also universal

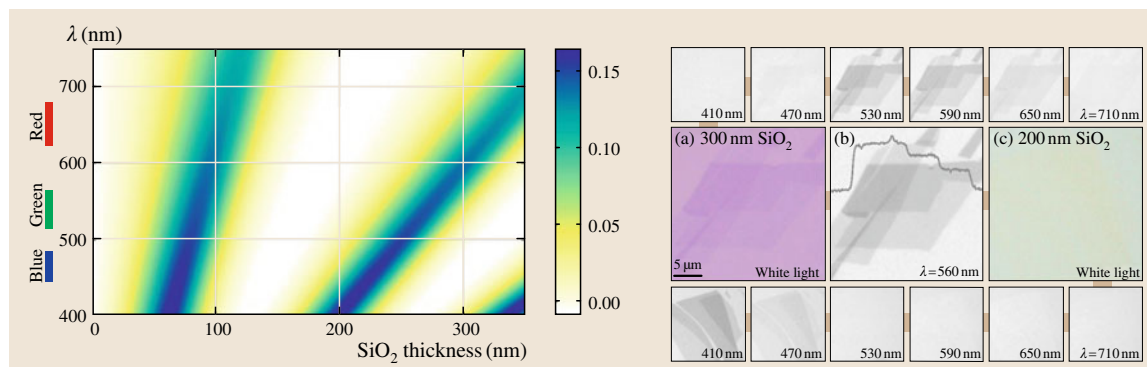

Fig. 2.15 Left: Color plot of contrast as a function of wavelength and SiO₂ thickness. The color scale on the right shows the expected contrast. Right: Graphene crystallites on 300 nm SiO₂ imaged with white light (panel a), green light, and another graphene sample on 200 nm SiO₂ imaged with white light (panel c). Single-layer graphene is clearly visible in the left image (panel a), but even three layers are indiscernible on the right (panel c). Image sizes are 25 × 25 μm². Top and bottom panels show the same flakes as in (panel a) and (panel c), respectively, but illuminated through various narrow bandpass filters with bandwidth of ≈ 10 nm (after [2.7])

and given by $T \equiv (1 + 2\pi G/c)^{-2} = (1 + 1/2\pi\alpha)^{-2}$ and $R \equiv 1/4\pi^2\alpha^2 T$ for normal light incidence. This yields graphene's opacity $(1 - T) \approx \pi\alpha = 2.3\%$.

2.2.5 Thermal and Thermoelectric Properties

CNTs are known to have very high thermal conductivity K with the experimentally determined value of $K \approx 3000$ W/(m K) at room temperature for an individual multi-walled CNT [2.119] and $K \approx 3500$ W/(m K) for an individual single-walled CNT [2.120]. These values exceed those of the best bulk crystalline thermal conductor, diamond, which has thermal conductivity in the range $K = 1000$ –2200 W/(m K) [2.121].

The first experimental determination of the thermal conductivity of suspended monolayer graphene pegged the value at 5300 W/(m K) and a phonon mean free path of 775 nm near room temperature [2.122], which was extracted from the dependence of the Raman G peak frequency on the excitation laser power and independently measured G peak temperature coefficient. Interestingly, this value is higher than the bulk graphite limit of $K \approx 2000$ W/(m K) [2.123]. It has been experimentally shown that the room-temperature thermal conductivity decreases from ≈ 2800 to ≈ 1300 W/(m K) as the number of graphene layers in few-layer graphene (FLG) increases from two to four [2.124]. The observed evolution from two-dimensional graphene to bulk graphite is explained by the cross-plane coupling of the low-energy phonons and changes in the phonon

Umklapp scattering, since more states are available for scattering owing to the increased number of phonon branches.

The thermoelectric power (TEP) is the voltage developed across a sample when a constant temperature gradient is applied. TEP of 80 μV/K was recently measured in graphene at room temperature (300 K) [2.125]. Similar to the quantum Hall effect in electronic transport, quantized TEP has also been observed in graphene at high magnetic fields [2.125]. The TEP can be tuned in graphene, even to negative values, under the application of a gate bias or chemical potential [2.126]. Very large TEP values have been predicted for graphene nanoribbons, for instance, 4 mV/K for a 1.6 nm-wide ribbon [2.127]. In comparison, the highest value experimentally reported so far is 850 μV/K for two-dimensional electron gases in SrTi₂O₃ heterostructures [2.128], while only a few μV/K has been reported for bulk graphite [2.123]. The TEP power of SWNTs has been theoretically and experimentally shown to be 60 μV/K [2.129], inferior to that of graphene. A giant thermoelectric coefficient of 30 mV/K was reported in a nanostructure consisting of metallic electrodes periodically patterned over graphene, deposited on a silicon dioxide substrate [2.130].

2.2.6 Chemical Properties

The chemistry of graphene is dominated entirely by its surface, since every carbon atom is a surface atom twice over, forming a part of two surfaces. For nanorib-

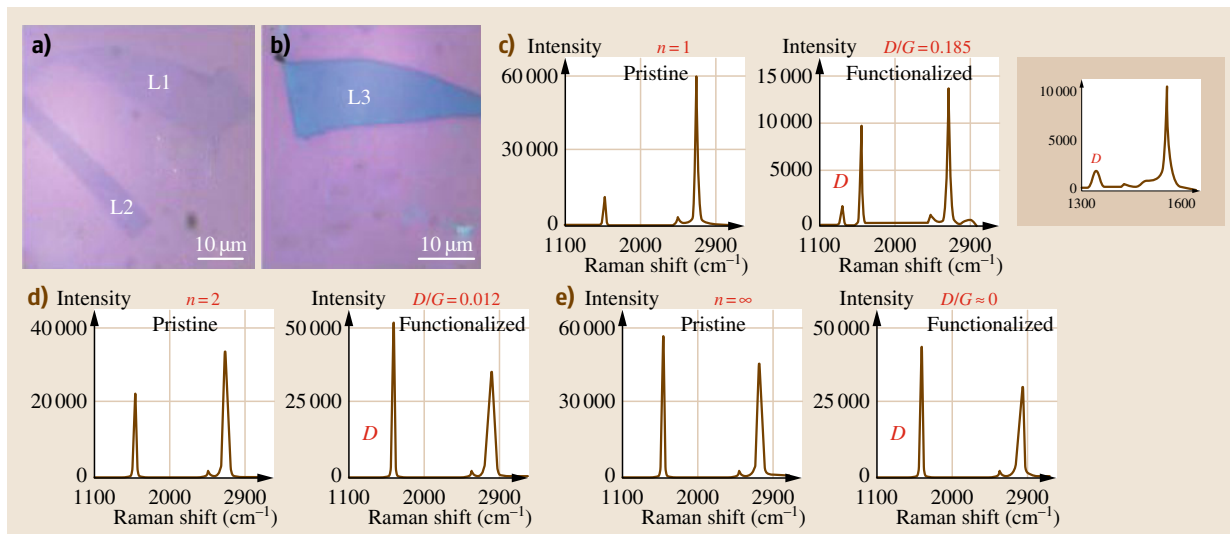

Fig. 2.16 (a) Microscopic images of single-layer (right), bilayer (left), and (b) multilayer ($n \approx \infty$) graphene. (c–e) Raman spectra of pristine (left) and functionalized (right) sheets: (c) spot L1 on single sheet with inset showing expanded 1300–1700 cm^{-1} region, (d) spot L2 on bilayer, and (e) spot L3 on multilayer ($n \approx \infty$, graphite). There is no D peak for the pristine samples (left spectra). The D/G ratio after reaction of single layer (0.185) is about 15 times higher than that for a bilayer (0.012) and greater for other multilayers (≈ 0). Reactions all performed at 35 °C with 17 mM 4-nitrobenzene diazonium water with 1 wt.% sodium dodecyl sulfate (SDS) (after [2.131])

bonds of graphene, the edges play an increasing role in determining their reactivity.

It has been shown that, for electron transfer chemistries, single graphene sheets are almost 10 times more reactive than bilayer or multilayer graphene (Fig. 2.16) according to the relative intensity of the disorder (D) peak in the Raman spectrum examined before and after chemical reaction [2.131, 132]. Substrate-induced doping of the graphene resulting in electron-rich regions has been proposed to explain this trend. The effect of doping is greatest in monolayers because the screening length in the c -axis in graphite and graphene is only 5 Å, comparable to the interlayer spacing of 3.5 Å [2.133, 134]. Similarly, the reactivity of edges is at least two times higher than the reactivity of the bulk graphene sheet [2.131]. Predictions based on Gerischer–Marcus electron transfer theory and tight-binding approximations predict that armchair and zigzag graphene nanoribbons (GNRs) have opposite trends in reactivity, with the former increasing with width and the latter decreasing. In zigzag ribbons the major reactivity contribution comes from edge states [2.135]. This reactivity trend for zigzag GNR is reversed for very narrow ribbons due to the presence of large semiconducting gaps with correspondingly low reactivities.

Graphene can be readily functionalized through diazonium or nitrene [2.136] reactions, which can introduce reactive species covalently linked to graphene. These groups then serve as templates for further chemistry and grafting of functional groups, for instance, through an azide linker. Chemical functionalization of graphene can be monitored through its effect on the conductivity of graphene, serving as a means to control the electrical transport properties of graphene [2.137, 138]. Furthermore, p-doped and n-doped regions in graphene can be generated by suitably functionalizing them, for instance, with diazonium salts and polyethylene imine, respectively [2.139]. Such chemical modification can also be performed on different parts of a single sheet to form p–n junctions in graphene [2.140].

2.2.7 Properties of Graphene Derivatives

Graphene was theoretically predicted to take one of two configurations: a *chair* conformer with the hydrogen atoms alternating on both sides of the plane for the two graphene sublattices, and a *boat* conformer with the hydrogen atoms alternating in pairs [2.79]. These chair and boat conformers have a direct electronic bandgap of 3.5 and 3.7 eV, respectively. Graphene is a com-

pletely insulating material; its resistivity changes by two orders of magnitude with decreasing temperature from 300 to 4 K, and its carrier mobility decreases to $\approx 10 \text{ cm}^2/(\text{V s})$ at liquid-helium temperatures for typical carrier concentrations of 10^{12} cm^{-2} [2.80].

Similarly, fluorographene [2.82] is a high-quality insulator with large optical bandgap of $> 3 \text{ eV}$ and room-temperature resistivity of $> 10^{12} \Omega$. The Young's

modulus of fluorographene was measured to be 0.3 TPa, which is about 30% the stiffness of graphene. Similarly, fluorination reduces graphene's intrinsic breaking strength by 2.5 times. However, fluorographene is able to sustain the same ultimate strain of 15% as graphene. Fluorographene is also strongly hydrophobic, and can be considered the two-dimensional equivalent of Teflon.

2.3 Characterization

Each of the properties discussed in the previous section has to be measured and correlated using multiple characterization techniques, which are discussed in this section; for instance, electronic properties of graphene have to be independently verified by ARPES, optical spectroscopy, and electronic transport. This is essential, since just one measurement, for instance, electronic transport, might not be able to sufficiently distinguish between an electronic bandgap and a mobility gap. Similarly, mechanical properties have to be confirmed by a combination of tensile testing, electromechanical resonance, and Raman spectroscopy.

2.3.1 Optical Characterization

Based on the optical properties of graphene discussed in an earlier section, and the fact that green light is most comfortable for the eyes, optimal SiO_2 thicknesses of 90 and 280 nm can be recommended [2.7]. Similarly, it has been shown that graphene can be observed on 50 nm Si_3N_4 using blue light and on 90 nm poly-methyl methacrylate (PMMA) using white light [2.7]. Optical contrast can similarly be used to identify graphene oxide on Si/SiO_2 substrates, as well as to visualize its conversion to reduced GO upon annealing, since both the effective index of refraction and the effective extinction coefficient increase [2.141].

Rayleigh scattering can identify the number of graphene layers as well as probe their dielectric constant [2.142]. Rayleigh imaging relies on elastically scattered incident photons, while Raman spectroscopy, which is discussed later, collects inelastically scattered photons. For graphene on Si/SiO_2 substrate, under white-light illumination combined with interferometric detection, the contrast can be tailored by adjusting the SiO_2 thickness and the light modulations depend strongly on the graphene thickness. Up to six layers, the graphene behaves as a superposition of single sheets and the monochromatic contrast increases linearly.

2.3.2 Transmission Electron Microscopy

Transmission electron microscopy (TEM) is one of the most direct observation techniques to elucidate the structure of graphene. High-resolution TEM can resolve individual carbon atoms as well as adatoms, defects, and other anomalies in graphene (Fig. 2.17) [2.88]. The high-energy electrons in a TEM can also be used to engineer defects such as vacancies, cause edge reconstructions and graphene sublimation, as well as observe them in situ [2.10]. Various techniques have been developed to transfer micromechanically cleaved graphene flakes onto TEM grids. If folds occur in the transferred graphene flake, observation of the folded edge can yield information about the number of layers in the graphene flake [2.9]; a monolayer fold edge turns up as a single dark line, while a bilayer fold edge appears as two dark lines and so on, in analogy to single-walled and multi-walled carbon nanotubes. In addition, nanobeam electron diffraction (Fig. 2.17) can also be used to quantify the layering in graphene [2.9]. Monolayer graphene can be distinguished from higher-layered graphenes by the anomalous intensity ratio of the diffraction peaks; its $0\bar{1}10$ peaks being more intense than the $1\bar{2}10$ peaks. When measured as a function of incidence angle, it probes the whole 3-D reciprocal space. The total (integrated) intensity of the $0\bar{1}10$ and $1\bar{2}10$ peaks of monolayer graphene varies weakly with tilt angle and no minima in intensity are observed, since the intensities in reciprocal space for monolayer graphene are continuous rods. In contrast, the total intensity of bilayer graphene diffraction peaks varies strongly with tilt angle, including minima at certain angles where some peaks vanish [2.143]. However, while the total intensity in monolayer graphene only decreases slightly, significant peak broadening is observed with increasing tilt angle. This effect is most pronounced in monolayers, and decreases with increasing thickness of the graphene flake. This is attributed to nanoscale corrugations in 2-D

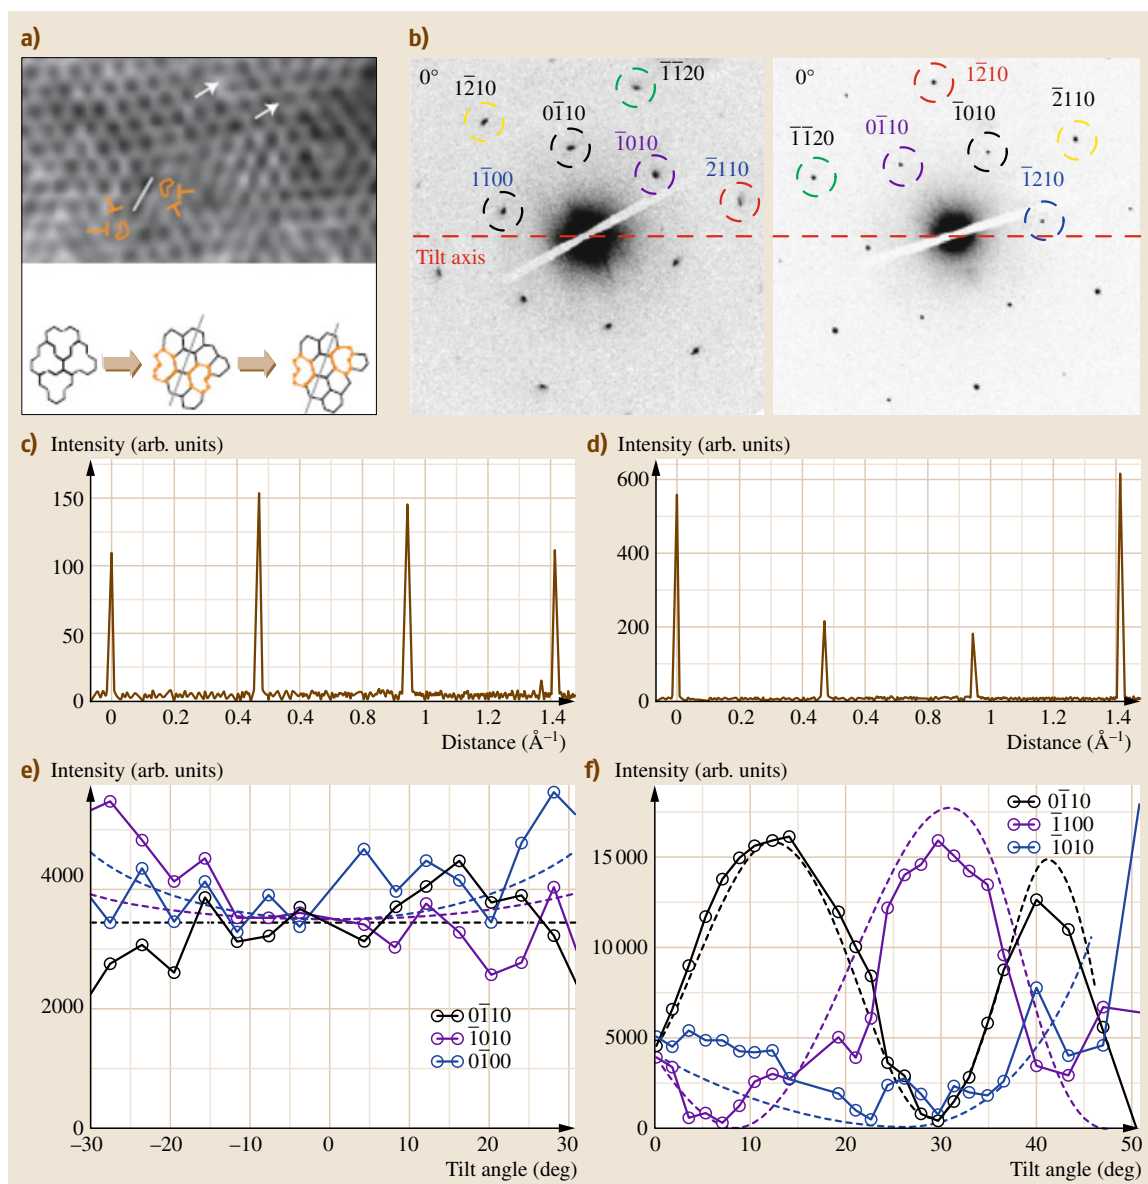

Fig. 2.17 (a) Atomic-resolution TEM of graphene (after [2.88]). (b) Nanobeam electron diffraction patterns of monolayer and bilayer graphene. Relative intensities of $1\bar{1}00$ and $1\bar{1}20$ peaks in (c) monolayer and (d) bilayer graphene. Variation of intensity of the $1\bar{1}00$ peaks with tilt angle for (e) monolayer and (f) bilayer graphene (after [2.143])

graphene, with the surface normal deviating on average by $\pm 5^\circ$ in monolayers and $\pm 2^\circ$ in bilayers. Considering that the spatial extent of these corrugations cannot be drastically smaller than the coherence length of the diffracted electrons and that a large number of orientations should be included within the submicron electron

beam in order to yield a smooth Gaussian shape of the diffraction peak, it is estimated that the corrugations occur on length scales of 10–25 nm. This nanoscale corrugation extending into the third dimension squares the existence of 2-D graphene with the theoretical prediction that perfect 2-D atomic crystals cannot exist.

The step height at the edge of the membrane is 2.5 nm. **(c)** Schematic of nanoindentation on suspended graphene membrane. **(d)** AFM image of fractured membrane (after [2.96])

2.3.3 Scanning Probe Techniques

Scanning probe techniques discussed here in the context of graphene characterization include atomic force microscopy (AFM), electrostatic force microscopy (EFM), and scanning tunneling microscopy (STM) and spectroscopy (STS).

AFM in tapping mode is commonly used to measure the thickness of graphene flakes on substrates; however, the correlation between measured thickness and actual thickness as well as number of layers is challenging [2.144]. Electrostatic interactions between the tip and the graphene, adsorbed moisture, and incorrect choice of AFM parameters such as free amplitude values can all influence the final measured thickness of a graphene flake. Therefore, while using AFM to characterize graphene flakes, an internal reference such as a fold in the flake, or a second characterization tool such as Raman spectroscopy, is often used to correlate the measured thickness and number of layers, and this

process needs to be repeated at least for every different substrate and processing conditions involved in the graphene preparation.

In addition, AFM is used to measure the flatness of graphene on various substrates, and it is revealed that ultraflat graphene can be obtained on mica surface [2.91] with standard deviation of height and height correlation length of 24.1 pm and 2 nm, respectively, compared with 154 pm and 22 nm, respectively, for SiO_2 substrate. AFM can also be used in nanoindentation mode to probe the stiffness of suspended graphene (Fig. 2.18) [2.96]. This technique has the advantage that the sample geometry can be precisely defined and the sheet is clamped around the entire hole circumference; a Young's modulus of 1 TPa and intrinsic breaking strength of 42 N/m have been measured. EFM has been used to confirm that the surface potential of few-layer graphene increases with film thickness, approaching bulk graphite values for five or more layers [2.145]. This is a measure of the extent of the electrostatic interaction between graphene and the substrate, and the screening of these perturbations by underlying graphene layers.

STM can image graphene with atomic resolution, and the correlation of the graphene hexagonal lattice to the direction of the edge of an exfoliated flake reveals the orientation of the edge as being either armchair or zigzag [2.146]. It has been shown that, in mechanically exfoliated graphene flakes, a majority of edges follow either of these orientations and intersect at angles that are multiples of 30° . STM imaging of graphene grown epitaxially on SiC [2.147] or metallic substrates [2.20, 23, 87, 148] reveals the superlattice structure and the extent of coupling between the graphene and substrate. STM can also be used to locate and characterize point defects in the graphene lattice [2.149, 150]. STS can be used to probe the atomically resolved local electronic structure of graphene [2.147, 151, 152]. A prominent gap in the tunneling spectrum unique to graphene has been observed and attributed to a phonon-mediated inelastic tunneling process.

2.3.4 Angle-Resolved Photoemission Spectroscopy (ARPES)

ARPES is a direct experimental technique that has measured the electronic density of states in graphene with both energy and momentum information. The shape of the π and π^* bands near E_F at the K-point from ARPES reveals the transition from 2-D to bulk character from one to four layers of graphene [2.153]. Fermi velocities and effective masses of the electrons

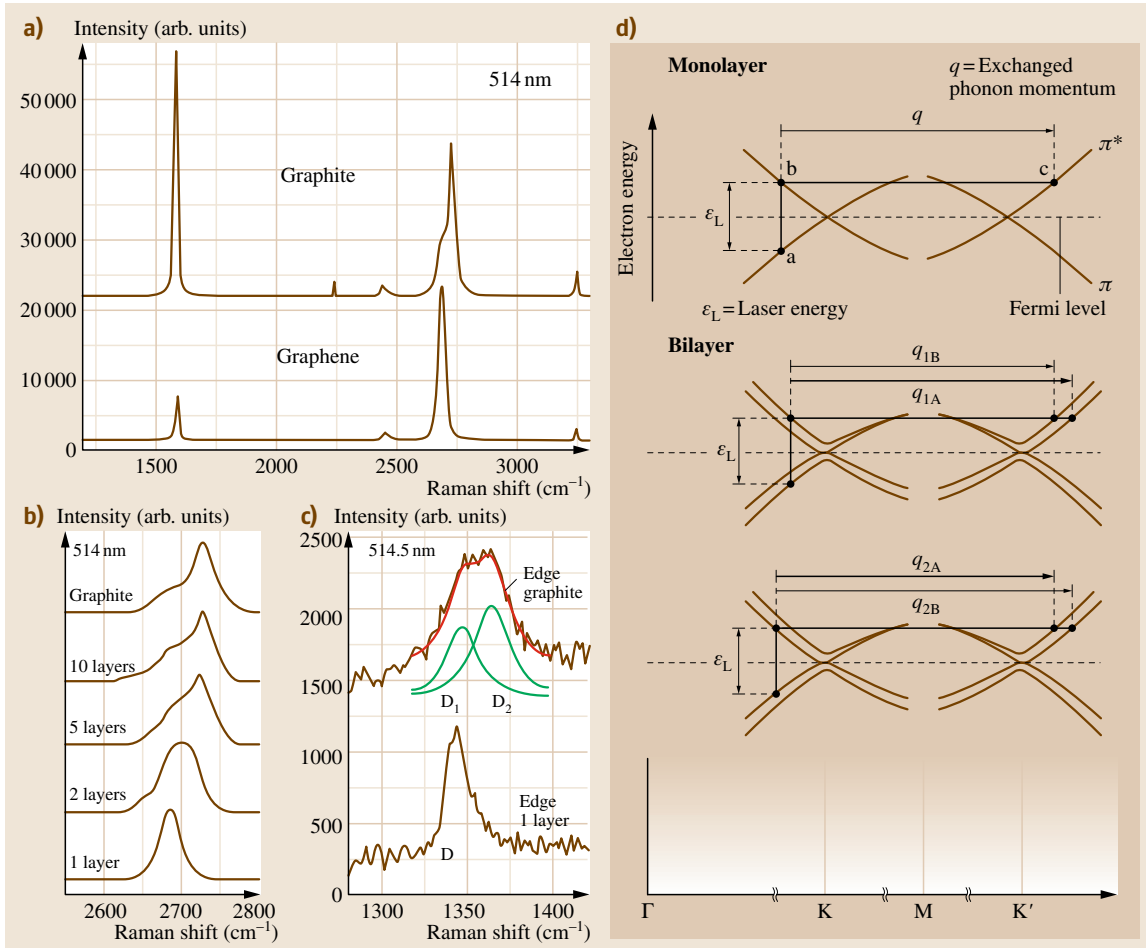

Fig. 2.19 (a) Comparison between Raman spectra of graphene and graphite. (b) Evolution of 2D peak shape with number of layers of AB-stacked graphene. (c) Comparison of D peak between graphene and graphite. (d) Scattering processing causing the 2D peak components in monolayer and bilayer graphene (after [2.156])

can also be measured. ARPES on epitaxial AB-stacked bilayer graphene on SiC has revealed that the magnitude of the gap between the valance and conduction bands can be varied by controlling the carrier density, for instance, with a transverse electric field. On the other hand, APRES also reveals that individual graphene layers of multilayer graphene grown on SiC(000 $\bar{1}$) behave as decoupled monolayers with independent linearly dispersed bands at the K-point [2.154]. ARPES also allows studies of electron–electron, electron–phonon, and electron–plasmon interactions, and indicates that all three must be considered on an equal footing in understanding the quasiparticle dynamics in graphene [2.155]. Ab initio simulations of the ARPES intensity spectra of

graphene has been able to reproduce key experimental observations including the indication of a mismatch between the upper and lower halves of the Dirac cone.

2.3.5 Raman Spectroscopy

The three significant Raman spectral features in graphene are the G peak at $\approx 1580 \text{ cm}^{-1}$, the D peak at $\approx 1350 \text{ cm}^{-1}$, and the 2D peak at $\approx 2700 \text{ cm}^{-1}$, as seen in Fig. 2.19 [2.156]. The G peak is due to the E_{2g} mode, i. e., in-plane vibrations of the carbon atoms. The D peak and 2D peak are strongly dispersive, with excitation energy due to the Kohn anomaly at the K-point, while the G peak is not.

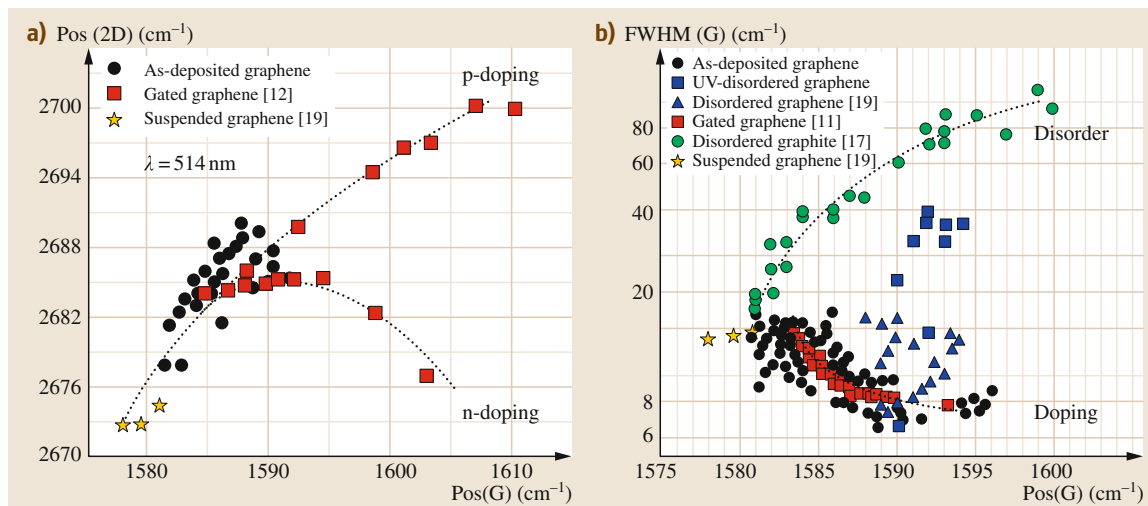

Fig. 2.20 (a) Pos(G) as a function of Pos(2D) for as-deposited graphene and gated graphene. (b) Pos(G) as a function of FWHM(G) for as-deposited graphene, compared with disordered graphene, disordered graphite, and gated graphene. The dotted lines are only a guide to the eye (after [2.159])

The 2D peak is the second order of the zone-boundary phonons and therefore does not require defects. For monolayer and few-layer graphene, the 2D peak serves as a fingerprint for identification [2.156]. In general, the 2D peak of graphite has four components: $2\text{-D}_{1\text{B}}$, $2\text{-D}_{1\text{A}}$, $2\text{-D}_{2\text{A}}$, and $2\text{-D}_{2\text{B}}$. Monolayer graphene has a single sharp 2D peak, dominated by the $2\text{-D}_{1\text{A}}$ component. In bilayer graphene, the $2\text{-D}_{1\text{A}}$ and $2\text{-D}_{2\text{A}}$ peaks have higher relative intensity compared with the other two, and the 2D peak appears up-shifted and broader compared with monolayer graphene. In monolayer graphene, there is only one phonon satisfying the double-resonance conditions for the 2D Raman peak. In bilayer graphene, the interaction between graphene layers causes the π and π^* electronic bands to split into four bands. According to density functional theory dipole matrix elements, the incident light couples more strongly to two among four possible optical transitions (Fig. 2.19). The excited electrons can be scattered by phonons with momenta $q_{1\text{B}}$, $q_{1\text{A}}$, $q_{2\text{A}}$, and $q_{2\text{B}}$. The corresponding processes for holes are associated to identical phonon momenta, resulting in four components to the 2D peak of bilayer graphene. As the number of layers further increases, the 2D_1 peaks reduce in intensity, and beyond five layers, it resembles the 2D peak of bulk graphite. It is also important to note here that non-AB stacked graphene, such as multilayer CVD graphene, also shows a single 2D peak [2.157, 158]. However, this can be distinguished

from monolayer graphene by its full-width at half-maximum (FWHM) of 50 cm^{-1} , which is twice that of monolayer graphene.

A similar observation can also be made for the D peak [2.156]. The D peak of monolayer graphene is a single sharp peak, while in bulk graphite it can be resolved into two peaks, D_1 and D_2 . The D peak is observed in defective graphene, and prominently at the edges of graphene flakes. In carbon nanotubes, confinement and curvature split the two degenerate modes of the G peak into G^+ and G^- components, whereas only one G peak is observed in graphene. The D peak arises from a double-resonance process involving electron scattering by zone-boundary phonons as well as defects in graphene. Since these do not satisfy the Raman selection rule, they do not occur in the Raman spectra of defect-free graphene. A similar process involving intravalley scattering gives rise to a D' peak at $\approx 1620 \text{ cm}^{-1}$ in defective graphene.

The Raman spectrum of graphene also responds to doping, i.e., changes in the Fermi surface of graphene [2.160, 161]. Graphene can be doped intentionally or unintentionally, by electron transfer from adsorbed chemical species, and by modulation of the electronic band structure by a gate voltage or interaction with the substrate. The G peak upshifts for both hole and electron doping. The position of the 2D peak, however, decreases monotonically with increasing electron concentration or decreasing hole concentration,

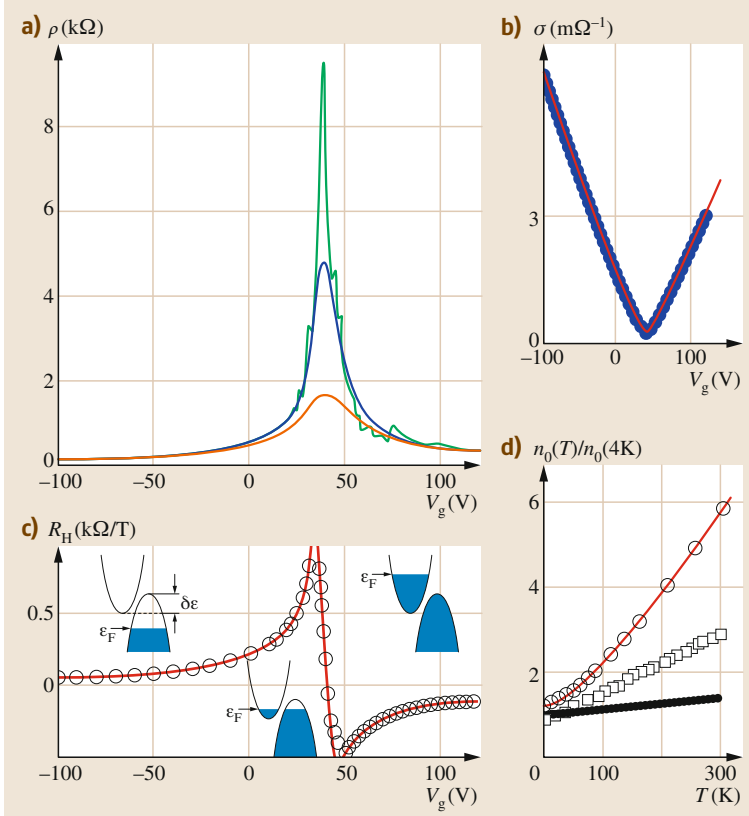

Fig. 2.21a–d Field effect in few-layer graphene. **(a)** Typical dependences of graphene’s resistivity ρ on gate voltage for different temperatures ($T = 5$, 70, and 300 K for *top to bottom* curves, respectively). **(b)** Example of changes to the film’s conductivity $\sigma = 1/\rho$ (V_g) obtained by inverting the 70 K curve (*dots*). **(c)** Hall coefficient R_H versus V_g for the same film at $T = 5$ K. **(d)** Temperature dependence of carrier concentration n_0 in the mixed state for the film in **(a)** (*open circles*), a thicker FLG film (*squares*), and multilayer graphene ($d \approx 5$ nm, *solid circles*). and the 2D peak can be used to distinguish between electron and hole doping. The changes in the G peak position are related to the nonadiabatic Kohn anomaly at the Γ point, while the shift in the 2D peak position is due to electron–electron scattering in addition to electron–phonon scattering. Taken together, a plot of 2D versus G peak positions can be used to distinguish between electron and hole doping in graphene (Fig. 2.20a) [2.159]. Doping trends can also be observed in the FWHM and intensities of Raman peaks. Raman peaks in graphene can also be shifted by biaxial strain induced, for example, by interaction with the substrate [2.162, 163]. It has been proposed that the correlation between normalized shift of 2D and G peak positions, i. e., $\Delta 2D/2D_0$ and $\Delta G/G_0$, where $2D_0$ and G_0 are the peak positions for undoped graphene, indicates whether the shift arises from doping or strain [2.164]. When $\Delta 2D/2D_0$ versus $\Delta G/G_0$ is plotted from Raman spectra obtained at a number of points on a graphene samples, a linear fit with slope close to 1.58 ± 0.18 indicates that strain plays a predominant role, while a smaller slope indicates in-

creasing influence of doping. Highly doped samples yield a slope of < 1 . In another approach, if the plot of FWHM versus position of the G peak is monotonically decreasing, it is related to doping, while if it is monotonically increasing, it is caused by strain or disorder (Fig. 2.20b) [2.161]. Under uniaxial strain, the G peak splits into two bands, G^+ and G^- , analogous to the effect of curvature on the G peak of carbon nanotubes [2.165].

2.3.6 Electrical Characterization

The first electrical characterization of graphene was carried out on micromechanically cleaved few-layer graphene flakes (Fig. 2.21) [2.4]. The sheet resistivity ρ of FLG flakes varies with applied gate voltage V_g , exhibiting a sharp peak of several kilohms and decaying to $\approx 100 \Omega$ at high V_g . The conductivity $\sigma = 1/\rho$ increases linearly with V_g on either side of the resistivity peak (conductivity valley). The Hall coefficient R_H reverses sign at the same V_g as the resistivity peak. This resembles an ambipolar semiconducting

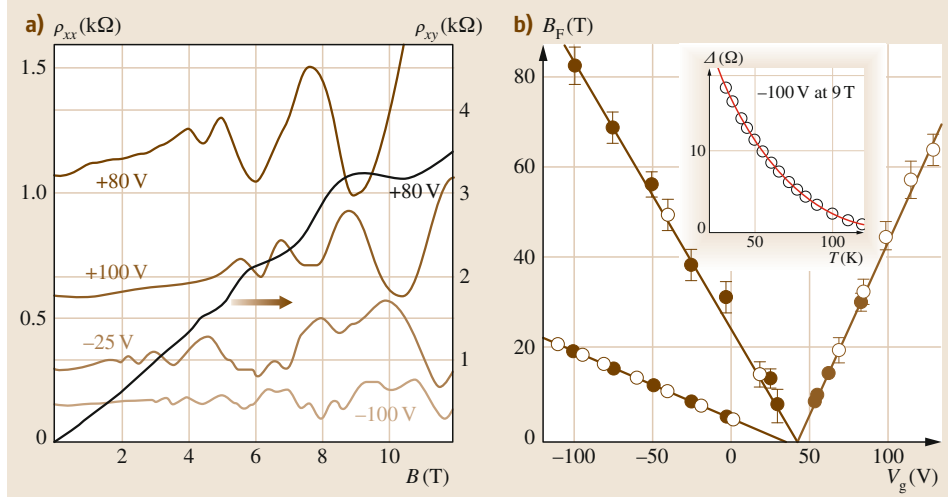

Fig. 2.22 (a) Examples of ShdH oscillations in a graphene device for different gate voltages; $T = 3$ K, and B is the magnetic field. (b) Dependence of the frequency of ShdH oscillations B_F on gate voltage. Solid and open symbols are for samples with $\delta\epsilon \approx 6$ and 20 meV, respectively. Solid lines are guides to the eye. The inset shows an example of the temperature dependence of amplitude % of ShdH oscillations (circles) (after [2.4])

field-effect transistor (FET), except that there is no zero-conductance region since there is no bandgap. This tunability of conductivity is achieved by transforming the graphene by electric-field doping from a completely electron to completely hole conductor, passing through a mixed state where both electrons and holes contribute equally. This behavior holds true for monolayer graphene as well as undoped bilayer graphene; however, doped bilayer graphene has an intrinsic bandgap and will be discussed subsequently. In both the electron and hole regions, R_H decreases with increasing carrier concentration as $1/ne$ as expected, and the resistivity follows the standard $\rho = 1/ne\mu$ relation, where μ is the carrier mobility. Also significant is the minimum conductivity of graphene at the charge neutrality point (σ_{\min}), which has been shown to be about $4e^2/h$. This σ_{\min} is not related to the physics of the Dirac point singularity, but instead related to charge-density inhomogeneities (electron–hole puddles) induced by the substrate or charged impurities [2.166, 167]. Invariably, the position of the charge neutrality point (ρ peak) is shifted to large positive V_g , leaving the ungated graphene as a hole metal. This large shift is attributed to unintentional doping of the graphene by adsorbed species such as water. The peak position can also be shifted by intentional doping [2.166] or removal of dopants by thermal or current-induced annealing [2.13], but such charged impurities do not affect σ_{\min} . The

mobility and minimum conductivity also decrease as a result of defects, which can be induced in a controlled fashion to study this effect, for instance, by ion irradiation [2.168] or exposure to atomic hydrogen [2.169].

The earliest determination of carrier mobility by field-effect and magnetoresistance measurements in few-layer graphene yielded $\approx 10\,000\text{ cm}^2/(\text{V s})$, which was independent of the absolute temperature, indicating that it was limited by scattering defects. For multilayer graphene, the mobility reached $15\,000\text{ cm}^2/(\text{V s})$ at 300 K and $60\,000\text{ cm}^2/(\text{V s})$ at 4 K. Substrate-induced charge puddles are significantly reduced in suspended graphene, and low-temperature mobility approaching $200\,000\text{ cm}^2/(\text{V s})$ has been reported [2.170, 171]. In such devices, the conductivity of suspended graphene at the Dirac point is strongly temperature dependent and approaches ballistic values at liquid-helium temperatures [2.171].

Graphene flakes also exhibit pronounced Shubnikov–de Haas (ShdH) oscillations in both longitudinal resistivity ρ_{xx} and Hall resistivity ρ_{xy} (Fig. 2.22). The oscillations depend only on the perpendicular component of the magnetic field $B \cos \Theta$, where Θ is the angle between the magnetic field and the graphene. The frequency of the SsdH oscillations B_F depends linearly on V_g , indicating that the Fermi energies ϵ_F of holes and electrons are proportional to their concentration n . This is different from the 3-D dependence ϵ_F proportional

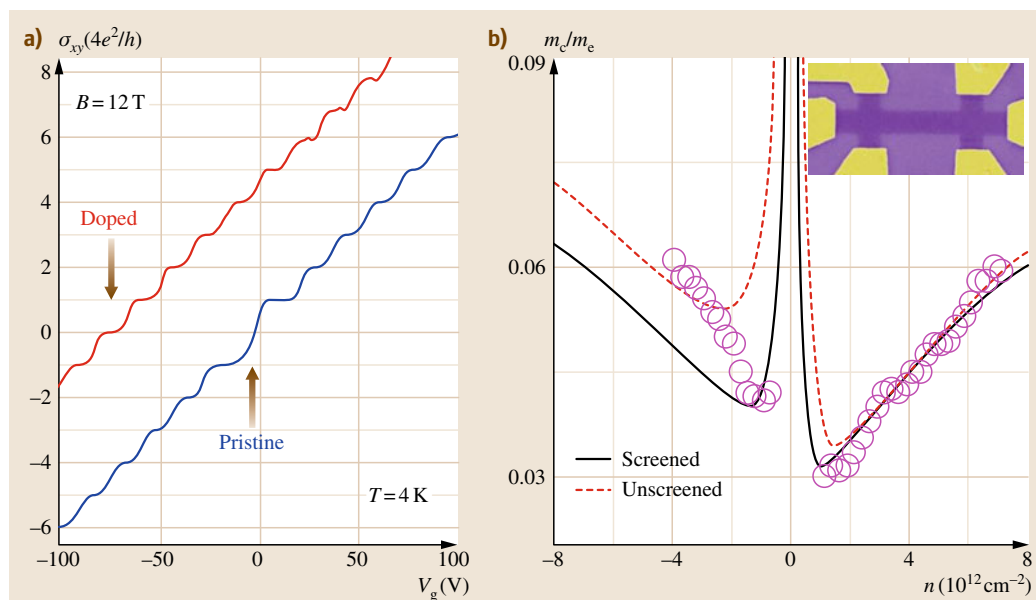

Fig. 2.23 (a) Measured Hall conductivity of pristine (undoped) and chemically doped bilayer graphene ($n_0 \approx 5.4 \times 10^{12} \text{ cm}^{-2}$), showing a comparison of the QHE in both systems. (b) Cyclotron mass versus n , normalized to the free electron mass m_e . Experimental data are shown as open circles. The inset shows an electron micrograph (in false color) of the Hall bar device with a graphene ribbon width of 1 μm (after [2.172])

to $n^{2/3}$, proving the 2-D nature of charge carriers in graphene.

QHE has been observed in graphene even at room temperature, since the electrons suffer little scattering due to their relativistic nature and have a large cyclotron gap which exceeds the thermal energy $k_B T$ by a factor of 10.

Under the influence of strong magnetic field, electrons in a two-dimensional system such as graphene develop strong Coulomb interactions between them, leading to correlated states of matter such as a fractional quantum Hall liquid. This collective behavior in graphene was predicted to yield the fractional quantum Hall effect (FQHE); however, due to prevalent disorder effects, observation of this remained elusive in early measurements. The FQHE was eventually reported in suspended graphene devices when a plateau at filling factor $\nu = 1/3$ was observed above a magnetic field as low as 2 T [2.173, 174]. An insulating state was also observed at magnetic fields $B > 5$ T and filling factors $\nu < 0.15$, which has been attributed to symmetry breaking of the zeroth Landau level by electron–electron interaction.

The first electron transport measurement of the tunable bandgap in bilayer graphene was conducted on

micromechanically cleaved graphene on an oxidized silicon wafer (300 nm SiO_2) [2.172]. The silicon substrate was used as a back gate to modulate the carrier density n , while doping from adsorbed NH_3 on the exposed graphene surface was used to mimic a top gate and open a bandgap corresponding to a fixed electron density n_0 . Under applied magnetic field, a plateau at zero Hall conductivity $\sigma_{xy} = 0$ occurs in biased bilayer graphene, as a result of the gap opened between the valence and conduction bands. Plateaus at $\sigma_{xy} = 4Ne^2/h$ occur as expected, including at $N = 0$ (Fig. 2.23a). This is the standard integer QHE that is expected for an ambipolar semiconductor with energy gap larger than the cyclotron energy. This plateau is absent in monolayer and unbiased bilayer graphene, which show an anomalous double step of $8e^2/h$ at $n = 0$, indicative of the metallic state at the charge neutrality point. A huge peak in the longitudinal resistivity ρ_{xx} at $n = 0$ was also observed, exceeding 150 k Ω at 4 K compared with 6 k Ω for the unbiased case. From Shubnikov–de Haas measurements, the cyclotron mass, m_c , in biased bilayer graphene is found to be an asymmetric function of the carrier density, which is a clear signature of a bandgap (Fig. 2.23b). Measurements with dual-gated bilayer graphene have also confirmed these results [2.175].

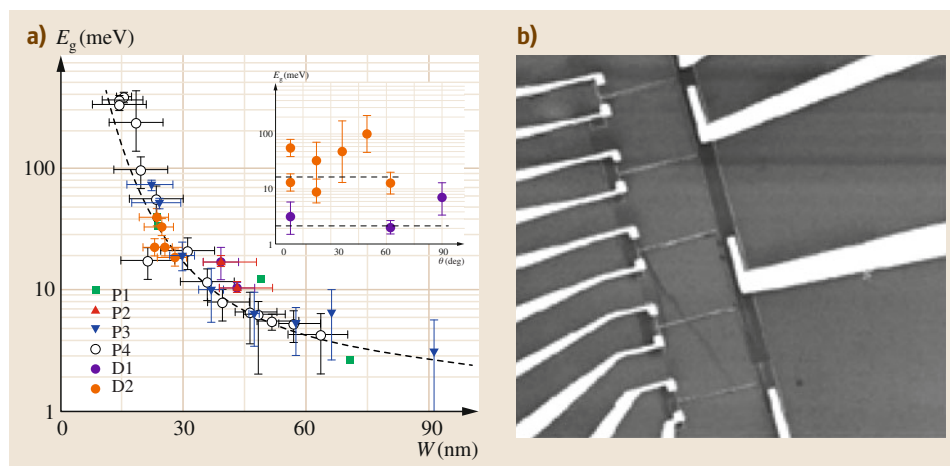

Fig. 2.24
(a) SEM image of a set of graphene nanoribbon devices of varying width. (b) Dependence of energy gap on ribbon width and orientation (inset). Dashed line shows the predicted empirical scaling (after [2.177])

Due to the linear dispersion relation in graphene, intrinsic electron scattering by acoustic phonons is independent of carrier density and only contributed $30\ \Omega$ to the room-temperature resistivity of graphene. This would yield an intrinsic mobility of $2 \times 10^5\ \text{cm}^2/(\text{V s})$ at carrier density of $1 \times 10^{12}/\text{cm}^2$, which would make it the highest known mobility, superior to those of InSb and semiconducting single-walled carbon nanotubes. However, a strong temperature dependence of mobility is observed in substrate-supported graphene devices, suggestive of extrinsic scattering, which limits the mobility to about $4 \times 10^4\ \text{cm}^2/(\text{V s})$ [2.176].

Various approaches have been proposed to increase the performance of graphene devices, in particular to reduce impurity scattering and enhance mobility. Ultrahigh current density-induced removal of adsorbents, photoresist, or e-beam resist residue can be used to clean graphene in situ during transport measurements [2.13]. A parylene-coated SiO_2 substrate used as a dielectric stack for back-gating yields a stable charge neutrality point and low hysteresis [2.178], since the hydrophobic nature of the parylene surface suppresses moisture-related doping and charge-injection effects and yields mobilities of up to $10\,000\ \text{cm}^2/(\text{V s})$. Similar results have been achieved by utilizing an organic polymer buffer between graphene and conventional top-gate dielectrics [2.179]. It was demonstrated that merely changing the dielectric to a high- k dielectric or media does not increase the carrier mobility beyond $\approx 10\,000\ \text{cm}^2/(\text{V s})$, suggesting that Coulomb scattering is not the dominant limitation beyond this regime [2.180]. Phonon scattering or resonant scatterers with energy close to the Dirac point have been proposed as alternate mechanisms.

As discussed previously, another route to opening a bandgap in graphene is to exploit lateral confinement of charge carriers in a graphene nanoribbon, which creates an energy gap near the charge neutrality point [2.177]. Graphene nanoribbons of varying widths and different crystallographic orientations have been fabricated by lithographic patterning of monolayer exfoliated graphene (Fig. 2.24). An energy gap is observed for narrow ribbons, which scales inversely with ribbon width. Energy gaps in excess of 100 meV were observed for widths less than 20 nm, which could have potential technological relevance. It has also been shown that edge states do not contribute to the dominant electrical noise at low frequencies for nanoribbons as narrow as 20 nm [2.181]. However, the lack of a well-defined crystallographic structure of lithographically etched edges means that the effect of orientation is not observed in the bandgap produced in such nanoribbons.

It is also possible to fabricate quantum dot (QD) devices entirely out of graphene using a similar lithographic procedure [2.182–184]. Such a device consists of a graphene island connected to the source and drain via two narrow graphene constrictions and three fully tunable graphene lateral gates (Fig. 2.25). Larger QDs ($> 100\ \text{nm}$) show conventional single-electron transistor characteristics, with periodic Coulomb blockade peaks. For smaller QDs, the peaks become strongly nonperiodic, indicating a strong contribution from quantum confinement. The narrow constrictions remain conductive and show a confinement gap of $\approx 0.5\ \text{eV}$. This can be extended to a double QD system (Fig. 2.25) where the coupling of the dots to the leads and between the dots is tuned by graphene in-plane gates [2.185]. This structure has been proposed for the realization of

Fig. 2.25 (a) SEM of an all-graphene single quantum dot device (after [2.184]). (b) SEM of an all-graphene double quantum dot device (after [2.185]). (c) Conductance of a graphene single QD device over a wide range of gate voltages at $T = 4$ K. (d) Zoom in to low-conductance region showing Coulomb blockade oscillations (after [2.182]). (e) Coulomb diamonds showing differential conductance as a function of gate voltage and drains–source bias

spin qubits from graphene QDs [2.186]. It has been shown that, in an array of many qubits, it is possible to couple any two of them via Heisenberg exchange while the others are decoupled by detuning. This unique feature is a direct consequence of the quasirelativistic nature of carriers in graphene.

One of the important considerations in electronic device performance is the signal-to-noise ratio, where usually the low-frequency $1/f$ noise dominates. In monolayer graphene, the $1/f$ noise follows Hooge's empirical relation with a noise level comparable to carbon nanotube and bulk semiconductor devices. However, in bilayer graphene, the $1/f$ noise is strongly suppressed and obeys a unique dependence on carrier density, due to effective screening of carrier scattering by external impurities [2.134]. In monolayer graphene, the noise amplitude is minimum at the Dirac point and increases with increasing carrier density. However, in bilayer graphene, the noise amplitude achieves a maximum at the Dirac point and decreases with increasing carrier density. In both cases, the noise is independent of carrier type.

In an effort to realize commercial viability of graphene electronics, reduced graphene oxide (RGO)

has been explored as an alternative to pristine monolayer graphene. However, measurements in individual monolayer RGO flakes have yielded conductivities ranging between 0.05 and 2 S/cm and field-effect mobilities of $2\text{--}200 \text{ cm}^2/(\text{V s})$ at room temperature. Conductivity decreases by up to three orders of magnitude when measured down to 4 K, following a $T^{-1/3}$ dependence, suggesting variable-range hopping conduction between regions of highly reduced (nearly pristine) graphene islands separated by defective or poorly reduced regions.

Spintronics

When graphene devices are fabricated with ferromagnetic electrodes, such as the soft magnetic NiFe or Co, it is possible to inject spin-polarized current into the graphene. A thin Al_2O_3 or MgO tunnel barrier is used at the ferromagnet–graphene interface. High-quality graphene enjoys ballistic transport with spin relaxation lengths between 1.5 and $2 \mu\text{m}$ even at room temperature, which is only weakly dependent on charge density [2.187]. The switching fields of the electrodes can be controlled by in-plane shape anisotropy. Graphene spin valves have been constructed using ei-

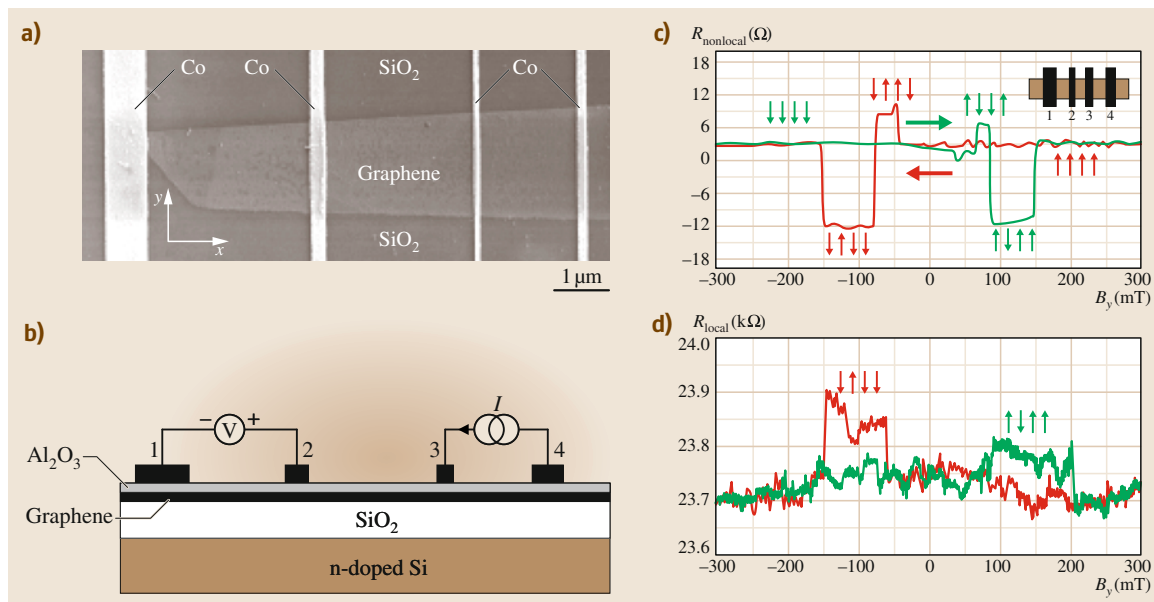

Fig. 2.26a–d Spin transport in a four-terminal spin valve device. **(a)** Scanning electron micrograph of a four-terminal single-layer graphene spin valve. **(b)** The nonlocal spin valve geometry. A current I is injected from electrode 3 through the Al₂O₃ barrier into graphene and is extracted at contact 4. The voltage difference is measured between contacts 2 and 1. **(c)** Nonlocal spin valve signal for device 1 at 4.2 K. The sweep directions of the magnetic field are indicated (red or green arrows). **(d)** A two-terminal local spin valve signal (measured between contacts 2 and 3) of about 60 V is measured at 4.2 K (after [2.187])

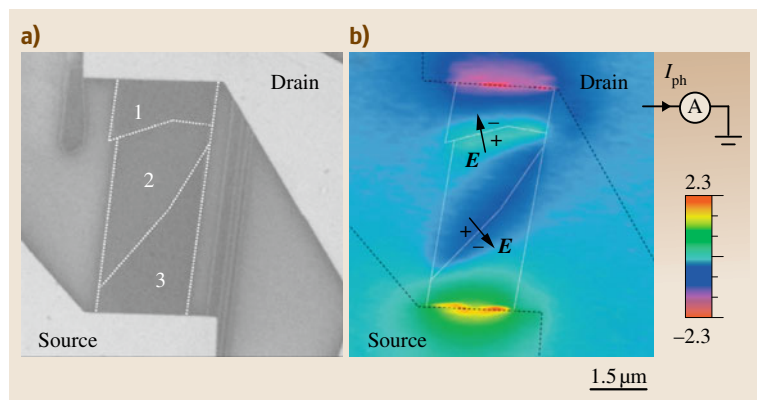

Fig. 2.27 (a) SEM image of the device. Region 2 consists of single-layer graphene, and regions 1 and 3 are multilayer. **(b)** Photocurrent image recorded in the p-type conduction regime. Black dashed lines indicate the edges of the source and drain electrodes. The white dotted lines mark the interfaces between single- and multi-layer graphene (after [2.190])

ther a local [2.188] or nonlocal [2.187, 189] geometry, and clear bipolar spin signal has been observed which is indicative of the relative magnetization directions of the electrodes (Fig. 2.26), and magnetoresistance of up to 12% has been reported in local geometry. In addition, Henle-type spin precession has also been reported, and a sign reversal in the spin signal can be achieved by applying an orthogonal switching magnetic

field. The nonlocal spin-valve signal changes magnitude and sign with back-gate voltage, and is observed up to $T = 300$ K [2.189].

An alternative configuration, comprising a graphene monolayer sandwiched between two ferromagnetic layers, involves spin-polarized conduction perpendicular to the plane of the graphene in a conduction perpendicular to plane (CPP) geometry [2.191]. Graphene

was sufficient to reduce the exchange coupling between the magnetic electrodes. In a NiFe/Au/graphene/NiFe stack, the graphene channels the spin current perpendicular to the plane and thus produces an enhanced magnetoresistance effect compared with a simple stack without the graphene.

2.3.7 Photocurrent Microscopy

The channel potential distribution in a graphene field-effect transistor can be imaged by scanning photocurrent imaging (Fig. 2.27) [2.190, 192]. When graphene is contacted to a metal, it is doped by the metal due to the work-function mismatch. The potential step between the graphene that is p-doped by a Ti-Pd-Au contact and

bulk graphene with no gate bias was estimated to be 45 meV. When light is shone on such potential steps which occur close to each contact, excited electron-hole pairs can be split by the potential gradient, leading to a photocurrent. At negative gate bias, before the flat-band condition, the graphene forms a $p-p^+-p$ channel. In the flat-band condition, the influence of the metal electrodes was measured to extend up to 450 nm into the graphene channel. For positive gate biases beyond the Dirac point, the graphene forms a $p-n-p$ channel, and when light is focused on the $p-n$ junction, an external responsivity of 0.001 A/W was measured. Scanning photocurrent microscopy has also revealed potential gradients occurring at monolayer-multilayer graphene interfaces [2.190].

2.4 Applications

While the field of experimental graphene research is still in its early years, graphene's potential for applications is already evident. Graphene is currently under evaluation for a wide range of applications, which will benefit from its unique combination of excellent mechanical, electronic, optical, and chemical properties. Commercial viability of most applications is severely limited by the limited options available for large-scale production of graphene. As a case study, graphene was proposed as an excellent transparent conductor with potential for replacing indium tin oxide (ITO), but it was not possible to pursue this application commercially until a roll-to-roll fabrication process for graphene was recently developed. Other applications, particularly in electronic devices, are critically dependent on breakthroughs in wafer-scale, complementary metal-oxide-semiconductor (CMOS)-compatible integration of individual graphene electronic devices.

2.4.1 Structural and Electrical Composites

The remarkable mechanical properties of graphene coupled with its high electrical and thermal conductivity suggest that it would be ideal for use in composite materials for structural as well as electronic applications. This potential has been enhanced by recent advances in solution-phase dispersion of graphene oxide (GO) and graphene, even down to highly monolayer-enriched graphene solutions. Graphene oxide-polystyrene composites show a low percolation threshold of ≈ 0.1 vol. % for room-temperature electrical conductivity and

≈ 0.1 S/m at 1 vol. %, which is sufficient for many electrical applications [2.54]. Such composites show ambipolar field-effect behavior with electron and hole mobilities of 0.2 and $0.7 \text{ cm}^2/(\text{V s})$, respectively [2.193]. GO-silica composites have been fabricated by spin-coating GO-impregnated silica sols to yield transparent conducting composite films [2.194]. Layered GO-polymer composites have been fabricated by layer-by-layer (LBL) assembly, taking advantage of electrostatic interactions between anionic GO sheets and cationic polymer [2.43]. Graphene oxide composites with poly(3-hexylthiophene) (P3HT) and poly(3-octylthiophene) (P3OT) have been demonstrated as a superior active layer in organic photovoltaics [2.195], while TiO_2 -graphene composite has been demonstrated as a high-performance photocatalyst [2.196]. Composites of functionalized graphene derived from GO with polymers such as PMMA, poly(acrylonitrile), and poly(acrylic acid) show the best performance in terms of Young's modulus, glass-transition temperature, ultimate strength, and thermal degradation [2.197]. Composites of graphene with metal nanoparticles (Au, Pt, and Pd) have also been produced, and the graphene-Pt composite has been demonstrated as a catalyst in direct methanol fuel cells [2.198].

2.4.2 Transparent Conducting Films

Thin films of graphene have been deposited from solution-phase graphene with controllable thickness from a single monolayer to several layers over large areas (Fig. 2.28) [2.199]. The thickness of the film de-

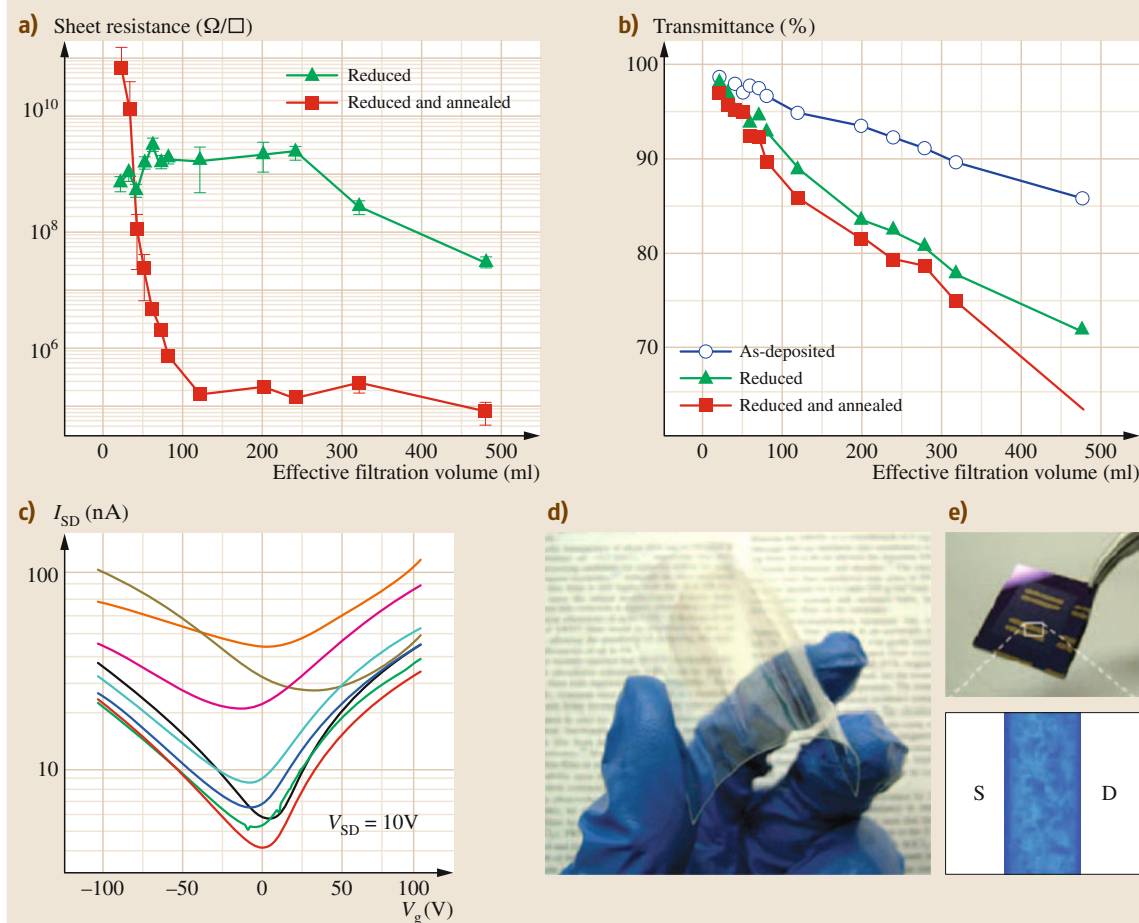

Fig. 2.28a–e Electrical and optical properties of reduced GO thin films. Sheet resistance (**a**) and transmittance (**b**) at $\lambda = 550$ nm as a function of filtration volume for reduced GO thin films. Plots are shown for thin films with different reduction steps. The sheet resistance for as-deposited GO thin films is out of scale. (**c**) Source–drain current as a function of gate voltage for 20 ml films measured at different temperatures in vacuum. (**d**) Photograph of GO thin films on filtration on a plastic substrate. (**e**) Optical micrograph of the actual device. The channel consists of several reduced GO sheets percolating across the source (S) and drain (D) electrodes. The channel length is 21 μm (after [2.199])

termines its conductivity, transparency, and mechanical integrity, making it suitable for various applications. Electronic properties can be tuned from graphene-like ambipolar field-effect behavior for the thinnest films to graphite-like semimetal conductivity for thicker films. Flow-based deposition, vacuum filtration, and layer-by-layer assembly are among the techniques used to deposit graphene thin films from solution. However, the predominant part of solution-phase research has involved reduced [2.200] or functionalized derivatives of graphene oxide, rather than pristine graphene.

Graphene conducting thin films are targeted at replacing indium tin oxide (ITO); however, it has so far been unable to match ITO's combination of 100 Ω per square sheet resistance at 90% transparency. Solution-processed reduced GO can be deposited as thin films of controllable thickness by Langmuir–Blodgett LBL deposition [2.201], and can achieve sheet resistance of 1 k Ω/\square per square at 90% transparency. Such films have been demonstrated as transparent conductive anodes for inorganic, organic, and dye-sensitized photovoltaic cells, but the short-circuit current and fill factor are still lower than those of control devices us-

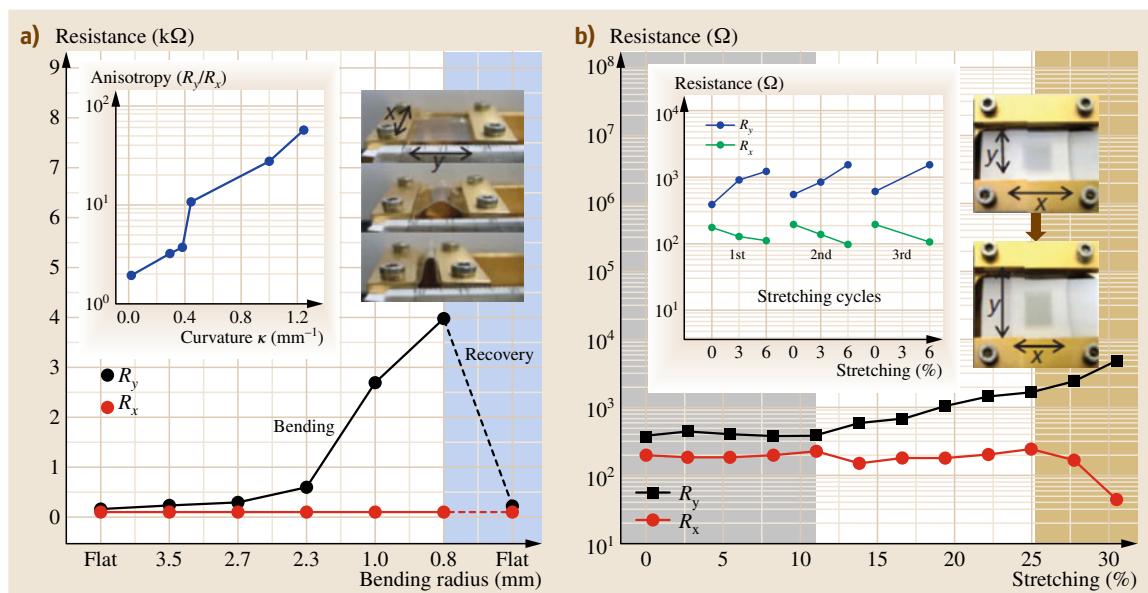

Fig. 2.29 (a) Variation in resistance of a graphene film transferred to a ≈ 0.3 mm-thick polydimethylsiloxane (PDMS)/polyethylene terephthalate (PET) substrate for different bending radii. The left inset shows the anisotropy in four-probe resistance, measured as the ratio R_y/R_x of the resistances parallel and perpendicular to the bending direction y . The right inset shows the bending process. (b) Resistance of a graphene film transferred to a PDMS substrate isotropically stretched by $\approx 12\%$. The left inset shows the case in which the graphene film is transferred to an unstretched PDMS substrate. The right inset shows the movement of holding stages and the consequent change in shape of the graphene film (after [2.204])

ing ITO [2.202,203]. However, they do have advantages such as tunable wettability, high chemical and thermal stability, and flexibility.

Pristine graphene films grown by chemical vapor deposition (CVD) on Ni or Cu substrates and transferred by a wet process can achieve $\approx 280 \Omega$ per square at $\approx 80\%$ transparency, but still fall short of ITO's benchmark. Still, the films show high electron mobility of $3700 \text{ cm}^2/(\text{V s})$ and exhibit the half-integer quantum Hall effect typical of high-quality graphene, which cannot be accomplished with reduced or functionalized GO (Fig. 2.29). Most importantly, the graphene films can recover its original resistance after being stretched by up to 6% and the resistance shows little variation up to bending radius of 2.3 mm, corresponding to tensile strain of 6.5%. This gives graphene films a significant advantage over ITO for applications in flexible electronics [2.204, 205]. A roll-to-roll dry transfer process has been developed for up to 30 inch monolayer (ML) graphene grown on Cu, yielding films with 97.4% transparency and 125Ω per square sheet re-

sistance (Fig. 2.30). The conductivity of graphene can be further improved by doping, for example, p-doping with HNO_3 , and resistance as low as 30Ω per square can be achieved at 90% transparency, making graphene a strong potential candidate for ITO replacement, particularly in flexible electronics [2.28].

Solution-processed graphene as well as CVD graphene have been demonstrated as electrodes for organic light-emitting diodes [2.206]. This, combined with graphene-based field-effect transistors and graphene transparent conducting electrodes, allows for fabrication of fully flexible and transparent touchscreen displays.

Graphene can be used as an electrode for polymer-dispersed liquid-crystal (PDLC) devices, for example, as a smart window. Light passing through the liquid crystal/polymer is strongly scattered, resulting in a milky film. If the liquid crystal's refractive index is close to that of the polymer, an electric field in the transverse direction causes the liquid crystals to align in the direction of light propagation, resulting in a transparent state [2.207].

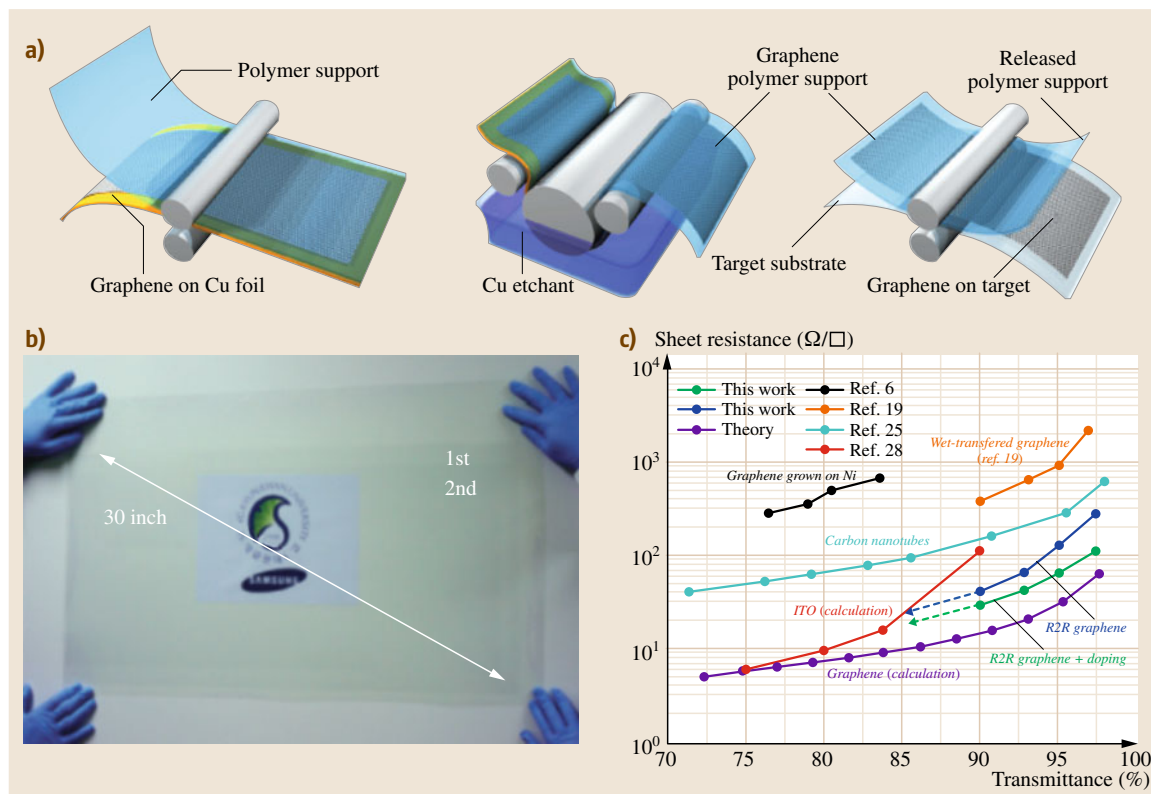

Fig. 2.30 (a) Schematic of roll-based production of graphene films grown on a copper foil. The process includes adhesion of polymer supports, copper etching (rinsing), and dry transfer printing onto a target substrate. (b) A transparent ultralarge-area graphene film transferred onto a 35 inch PET sheet. (c) Comparison of sheet resistance from this research and transmittance plots taken from other publications. The dashed arrows indicate the expected sheet resistances at lower transmittance (after [2.28])

2.4.3 Sensors

The ultimate detection limit of any chemical sensor is the ability to detect individual molecules of a desired species (Fig. 2.31). The exceptionally low-noise electronic characteristics of graphene allow for such single-molecule sensitivity [2.208]. Adsorbed gas molecules change the local carrier concentration one electron at a time, which can be detected as stepwise changes in device resistance.

Depending on the nature of the adsorbed species, the graphene can be either electron doped (NH_3) or hole doped (H_2O , NO_2). As there is no gap in the graphene density of states, even a small mismatch in chemical potential to the adsorbate is sufficient to provide an active donor or acceptor level, whereas in semiconductors, the chemical potential mismatch has to exceed half the gap energy to achieve doping [2.209]. Therefore, graphene

sensors are expected to be more sensitive than conventional semiconductor sensors.

Reduced graphene oxide-based devices have shown parts-per-billion sensitivity to chemical warfare agents and explosives [2.210], and parts-per-million sensitivity to gasses such as NO_2 and NH_3 [2.211]. Reduced GO-based sensors have also been demonstrated in surface acoustic wave configuration, with parts-per-million sensitivity to H_2 and CO [2.212]. Electrolyte-gated graphene devices have been demonstrated as pH and biomolecule sensors with picomolar sensitivity [2.213].

Suspended graphene resonators can be electrically or optically actuated and detected, with fundamental mode frequencies in the MHz range [2.214]. Molecular structural mechanics modeling has shown that the principle frequency vibrations of monolayer graphene are sensitive to added mass of $\approx 10^{-6}$ fg [2.215]. Mass sensitivity of ≈ 2 zg has been experimentally demonstrated

Fig. 2.31a–c Single-molecule detection. **(a)** Examples of changes in Hall resistivity observed near the neutrality point ($|n| < 10^{11} \text{ cm}^{-2}$) during adsorption of strongly diluted NO_2 (blue curve) and its desorption in vacuum at 50°C (red curve). The green curve is a reference – the same device thoroughly annealed and then exposed to pure He. The curves are for a three-layer device in $B = 10 \text{ T}$. The grid lines correspond to changes in ρ_{xy} caused by adding one electron charge e ($\delta R \approx 2.5 \Omega$), as calibrated in independent measurements by varying V_g . **(b–c)** Statistical distribution of step heights δR in this device without its exposure to NO_2 (in helium) **(b)** and during a slow desorption of NO_2 **(c)**. For this analysis, all changes in ρ_{xy} larger than 0.5Ω and quicker than 10 s (lock-in time constant was 1 s , making the response time $\approx 6 \text{ s}$) were recorded as individual steps (after [2.208])

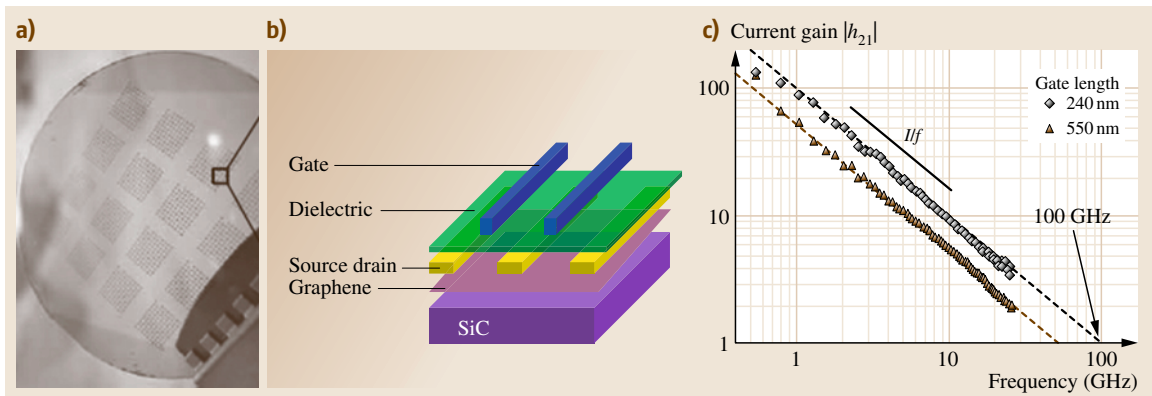

Fig. 2.32 **(a)** Image of devices fabricated on a 2 inch graphene wafer and **(b)** schematic cross-sectional view of a top-gated graphene FET. **(c)** Measured small-signal current gain $|h_{21}|$ as a function of frequency f for a 240 nm gate (\diamond) and a 550 nm gate (\triangle) graphene FET at $V_D = 2.5 \text{ V}$. Cutoff frequencies, f_T , were 53 and 100 GHz for the 550 and 240 nm devices, respectively (after [2.216])

using graphene resonators with a high quality factor of 14 000 at low temperature [2.102].

2.4.4 Electronic Applications

Charge carriers in graphene have very high mobility, which is not significantly affected by doping, leading to ballistic transport on a submicron scale even at room temperature. This is a much sought-after characteristic for the next generation of electronic materials,

since it would allow for very fast switching times, perhaps less than 10^{-13} s . The low on–off ratio (< 100) in gapless graphene is not a fundamental limitation for high-frequency operation. Transistors fabricated on epitaxial graphene on SiC have achieved a cutoff frequency of 100 GHz (Fig. 2.32) [2.216], and those fabricated on conventional Si/SiO₂ substrates have reached a cutoff frequency of 26 GHz [2.217].

Large-scale integration of graphene devices can be achieved either by conventional top-down fabrication

in the case of epitaxial graphene on SiC [2.218], or CVD graphene grown on metallic substrates and transferred to dielectric substrates. In the case of solution-phase graphene, bottom-up approaches such as dielectrophoretic trapping can achieve similar ultralarge-scale integration densities [2.219].

2.4.5 Photonics and Optoelectronics

Graphene enjoys broadband absorption of light, and therefore does not suffer from the *long-wavelength limit* of semiconductors, which become transparent at inci-

dent energies smaller than their bandgap. As a result, graphene-based photodetectors have been demonstrated to work over a much broader wavelength range. The photoresponse does not degrade for optical intensity modulations up to 40 GHz, with ultrafast response due to the high carrier mobility in graphene [2.220]. Graphene can also be used as the nonlinear saturable absorber in mode-locking for ultrafast laser systems, which turns a continuous wave into a train of ultrafast optical pulses [2.221, 222]. Graphene dispersions have been used as wideband optical limiters covering the visible and infrared regions of the spectrum [2.223].

2.5 Conclusions and Outlook

The field of graphene research is still very much in its early stages, with a majority of researchers devoted to exploring the fundamental properties of graphene. Not only is graphene a new material; it is also quite literally a new dimension of possibilities. A lot of mystery still surrounds this exciting new material, and often one finds that theoretical predictions are well ahead of experimental data in an emerging field such as this. Exciting physics that only occurs in two dimensions and that was previously inaccessible in experiments is now being sought, and new results are published regularly. Now that graphene has laid to rest the question of whether two-dimensional materials can exist in a stable self-supported form, researchers have started the hunt for other such 2-D materials. Boron nitride is one of the candidates to attract significant attention, particularly for its potential in combination with graphene.

Only recently, applications of the extraordinary properties of graphene have been experimentally demonstrated, and a still greater number of potential applications are still on the drawing board. In fact, only recently has bulk production of graphene in sheet

or solution form been achieved, but the economies of scale are still unfavorable for mass application. The commercial prospects of graphene remain unexplored, but it is hoped that, in the near future, the substantial research and investment into graphene will be vindicated. However, for a scientist motivated by the quest for new knowledge and understanding, graphene continues to reap rich rewards, as evidenced by the numerous results included here that were only published for the very first time during the duration of writing this chapter.

Lastly, it should be noted that graphene is a rapidly evolving field, and since the writing of this chapter, a large number of papers have been published covering every aspect discussed here. In many cases, these subsequent publications have added new knowledge about graphene, or provided better or even a different understanding of known phenomena. Consequently, the information compiled in this chapter should serve as a starting point for the reader to further investigate the properties, characterization and applications of graphene by referring to the latest publications.

Fullerenes and Beyond

3. Fullerenes and Beyond: Complexity, Morphology, and Functionality in Closed Carbon Nanostructures

Humberto Terrones

Part A | 3

The discovery of buckminsterfullerene 25 years ago opened a new field in materials science in which different disciplines such as physics, chemistry, medicine, mathematics, and engineering came together. This discovery is a clear example of what we now call nanoscience, thus having important implications for several applications in what is known as the nanotechnology of carbon materials. In this chapter, a revision of the most important advances in this area, involving the multidisciplinary of the field, is given. Special emphasis is given to the geometry, production methods, physicochemical behavior, applications, future perspectives, and the relationship to other layered materials such as graphene, boron nitride, and metal chalcogenides.

Twenty-five years after the discovery of buckminsterfullerene or C₆₀ [3.1], the field has matured, and besides the fundamental science involved, different applications have been found and others are waiting to be discovered. Eleven years after the discovery of C₆₀, the Nobel Prize in Chemistry was awarded to Harold

Kroto, Robert Curl, and Richard Smalley; According to the ISI Web of Knowledge [3.2] the original manuscript of *Kroto* and colleagues [3.1] has been cited around 7000 times by other scientific papers, and the term *fullerene* appears in more than 14 000 scientific publications. Not only C₆₀ has been recognized as im-

Fig. 3.1 (a) Buckminsterfullerene or C_{60} , (b) carbon nanotube, and (c) graphene piece

portant; other carbon nanostructure discoveries such as nanotubes [3.3, 4] have accumulated more than 10 000 citations in the scientific literature. Moreover, *André Geim* and *Konstantin Novoselov* were awarded the Nobel Prize in Physics in 2010 for the first experiments with few-layer graphite and graphene (a single layer of graphite, one atom thick), the flat cousin of C_{60} [3.5, 6] (Fig. 3.1).

However, there are more carbon nanostructures that need to be studied further, such as carbon onions (the bigger cousins of fullerenes) [3.7] and porous carbons [3.8]. In addition, fullerene research has opened a new field in nanoscience which involves layered materials such as boron nitride, molybdenum sulfide, tungsten sulfide, and other metal chalcogenides [3.9–14]. Even thin layers of metal oxides such as zinc oxide have been studied theoretically as layered structures due to their high stability and possible magnetic behavior [3.15].

Although the discovery of C_{60} as a spherical icosahedral (I_h) carbon molecule was reported in 1985 [3.1], other researchers thought about it before. *Schultz* in 1965 showed the possibility of having different kinds of carbon hydrogenated cages, among them the I_h truncated icosahedron of C_{60} [3.16]. In 1970, *Osawa* published a paper in the Japanese journal *Kagaku* showing that C_{60} was a possible structure [3.17]. *Orville L. Chapman* started the first experiments towards chemical synthesis of C_{60} at the beginning of the 1980s, before the discovery of C_{60} .

What really pushed the field of fullerenes forward was the method to synthesize large amounts of C_{60} published by *Krättschmer* and colleagues in 1990 [3.18] using an electric arc discharge. At the same time, it was also found that C_{60} crystallized in a face-centered cubic lattice (Fig. 3.2), forming a molecular crystal in

Fig. 3.2 The face-centered cubic (fcc) cell of fullerite of C_{60}

which the C_{60} molecules exhibit disorder because they are rotating.

C_{60} illustrates the multidisciplinary of nanoscience, involving topics in different fields mentioned herein such as new composite materials for more efficient so-

lar cells, virus inhibition, superconductivity, lithium-ion batteries, drug delivery, nanoelectronics, etc. All these show the amazing world of carbon and represent the tip of the iceberg of new carbon materials for the 21st century and beyond.

3.1 Geometry and Structural Features of Fullerenes

Perhaps the most interesting features of C_{60} are its round shape and its high symmetry (I_h). In this section, the geometry and mathematics of different possibilities for sp^2 nanostructures, including fullerenes, are presented, emphasizing the versatility of carbon to generate different shapes. The concept of Gaussian curvature is introduced in the context of graphite nanostructures, and the possibilities of nonclassical fullerenes are discussed. It is worth saying that the possibilities for carbon to form different nanoarchitectures are enormous, and it is up to researchers to try to find new ways to synthesize them.

3.1.1 The Mathematics of Closed Carbon Nanostructures

Buckminsterfullerene, or C_{60} , is just one case in which a nanostructure can acquire curvature to avoid dangling bonds and become more stable. There are other cases such as carbon onions [3.7], inorganic onions of MoS_2 or WS_2 [3.11, 12], and carbon nanotubes [3.3, 4]. However, to better understand the role of curvature in layered materials, we have to consider the restrictions imposed by mathematics.

It turns out that we live in a three-dimensional space (3-D) and all our atoms form structures in this space (space-time is not considered in our approach); therefore, everything that exists does so in this 3-D space. In 3-D space there are just three geometries: Euclidean, spherical, and hyperbolic, so nature is restricted to these geometries to form everything which surrounds us.

Euclidean or planar geometry is the one most commonly taught in schools, and one of its main features is that no curvature is present (everything is flat), for example. If we measure the interior angles of a triangle on a flat surface, they will add to exactly 180° . However, this is not the case for the other two geometries. If a triangle is drawn on the surface of an orange, its interior angles will measure more than 180° , and if we do the same experiment on the surface of a horse saddle or a seaweed the interior angles of the triangle

will add to less than 180° . Nature uses this, and that is why, at different levels of complexity, different shapes are observed in which not just Euclidean geometry is valid.

Another characteristic of 3-D space is that the surfaces immersed in it exhibit just two principal curvatures (C_1 and C_2). The product of these curvatures is called the *Gaussian curvature* K ($K = C_1 C_2$) and the average is called the *mean curvature* $H = (C_1 + C_2)/2$. According to the sign of the Gaussian curvature we can identify the geometry to which a particular point on a surface belongs. In the case of Euclidean geometry, both or one of the principal curvatures is zero and therefore $K = 0$. On the surface of a sphere, all the points possess principal curvatures with the same sign, and thus the Gaussian curvature is always positive everywhere. In hyperbolic geometry, the principal curvatures have different signs, and thus their product is always negative; this means that the points are saddle points and curve in opposite directions. In nature, at different levels of complexity, including the atomic level, it is possible to identify objects with zero, positive, and negative Gaussian curvature.

3.1.2 Carbon Nanostructures with Zero, Positive, and Negative Gaussian Curvature

Graphite is as a crystal formed by carbon atoms forming hexagonal layers and belongs to space group $P63/mmc$. One single layer of graphite is called graphene. In graphene, both principal curvatures are zero, thus belonging to the Euclidean geometry. However, if in a small piece of graphene, 12 pentagonal rings of carbon are introduced, then C_{60} can be formed. In C_{60} , both principal curvatures are positive, and it thus belongs to spherical geometry (Fig. 3.3a,b). A graphene sheet can also be bent to form a tube (a single carbon walled nanotube) and thus will show curvature (one of the principal curvatures is not zero and is the inverse of the radius of the tube $C_1 = 1/r$, where r is the radius of

Fig. 3.3 (a) Introduction of one pentagon in a graphitic piece induces positive Gaussian curvature (*up view*). (b) Side view of (a). (c) Introduction of a heptagon in a graphitic piece induces negative Gaussian curvature (*up view*). (d) Side view of (c) ◀

all points ($K = 0$). Therefore, the carbon nanotube belongs to Euclidean geometry. To confirm this, a triangle drawn on a sheet of paper will have the same interior angles if the sheet is rolled up to form a tube, since the paper cannot be deformed like rubber.

Structures with hyperbolic geometry have been proposed [3.8, 19–22] by the introduction of carbon rings with more than six carbon atoms, heptagons, octagons, and so on (Figs. 3.3c,d, 3.4). These periodic arrangements, with holes that divide space into two congruent regions, have been called schwarzites in honor of the German mathematician *Hermann Amandus Schwarz* (1843–1921) who was the first to find that negative curvature arrangements can produce periodic surfaces with zero mean curvature everywhere [3.23]. Mathematicians have defined a minimal surface as a surface that exhibits zero mean curvature at all points; therefore, minimal surfaces are surfaces formed by symmetric saddle points. Schwarzites are topological representations of minimal surfaces at the atomic level.

Considering Euler's Law, the Gauss–Bonnet theorem, and that in graphitic sp^2 structures every carbon atom is shared by three faces and every edge is shared by two faces, one has $2n_4 + n_5 - n_7 - 2n_8 = 12(1 - g)$, where n_4 , n_5 , n_7 , and n_8 are the number of squares, pentagonal, heptagonal, and octagonal rings of carbon in the nanostructure and g is the genus or number of handles in the graphitic arrangement. A sphere has genus zero (no handles), and a torus has genus 1 (one handle). The equation above can be applied to closed graphitic structures; that is, they do not exhibit boundaries. In the case of C_{60} and other classical fullerenes, there are just 12 pentagons (no squares, no heptagons, and no octagons) so $g = 0$, which is the same genus as the sphere.

In the case of the infinitely periodic schwarzites the genus per primitive cell is greater than or equal to 3. As the genus increases, the structure becomes more complex, as can be seen in Sect. 3.4.5 of this chapter, devoted to high-genus fullerenes.

3.1.3 Classical and Nonclassical Fullerenes

the nanotube); however, the total Gaussian curvature is zero, because one of the principal curvatures is zero at

A fullerene can be defined as a closed carbon shell in which each carbon atom is shared by three neighbors.

Classical fullerenes contain hexagonal rings and, as we have seen, 12 pentagonal rings of carbon (Fig. 3.5a–c). The pentagons are responsible for introducing the positive Gaussian curvature that characterizes fullerenes. Twelve pentagons are needed to achieve the closure of the structure, thus having exactly the angular deficit of the sphere (4π).

Nonclassical fullerenes exhibit rings with fewer or more than six carbon atoms, such as squares or heptagons. For each heptagon included, an additional pentagon is needed to compensate for the negative Gaussian curvature of the heptagon (Fig. 3.5d). Fullerenes in which there are six squares can also be considered as nonclassical.

Experimentally it is found that the most abundant fullerene is C_{60} or buckminsterfullerene, synthesized by Kroto and colleagues in 1985 using a laser and a graphite target [3.1]; C_{70} and higher fullerenes can also be obtained using this technique. A different way for synthesizing fullerenes is by electric arc discharge, which was used by Krätschmer and colleagues in 1990, leading to the discovery of fullerite (the solid form of C_{60}), which is composed of a molecular crystal formed by C_{60} molecules arranged in a face-centered cubic (fcc) structure (Fig. 3.2) [3.18]. Other fullerenes were synthesized afterwards, such as C_{76} , C_{84} , C_{90} , etc. [3.24]. The truncated icosahedral structure (I_h) of C_{60} and the elongated shape of C_{70} have been confirmed by ^{13}C nuclear magnetic resonance (NMR) spectroscopy [3.25, 26].

Despite the existence of 1812 possible ways of forming a classical fullerene with 60 carbon atoms, the most stable and symmetric is the I_h isomer. The number of isomers increases exponentially as the number of carbon atoms increases (Table 3.1). For nonclassical isomers with one heptagon the number of isomers increases even more [3.27].

One feature that makes C_{60} stable is that every pentagon is isolated from the others by hexagons, lead-

Table 3.1 Number of classical and nonclassical isomers with one heptagonal ring of carbon

Fig. 3.5 (a) Classical C_{40} fullerene with T_d symmetry. (b) Classical C_{70} fullerene with D_{5h} symmetry. (c) Classical C_{80} fullerene with I_h symmetry. (d) Nonclassical C_{62} fullerene with 1 heptagon (in color) and 13 pentagons

ing to the isolated pentagon rule (ipr) in fullerenes; therefore, fullerenes with adjacent pentagons cost more energy [3.28]. The next classical fullerene that exhibits isolated pentagons is C_{70} with D_{5h} symmetry, which

also has been identified experimentally [3.1,25,26]. For classical fullerenes with fewer than 60 carbon atoms there are no isolated pentagons, which is one of the reasons why they are not very stable [3.28].

3.2 Methods of Synthesis of Fullerenes and Proposed Growth Models

In this section different methods for obtaining C_{60} and other fullerenes are discussed. Most of the methods to produce C_{60} involve very high temperatures (around 4000 °C), such as laser vaporization and arc discharge, because these deal with solid graphite. However, there are other methods which work at lower temperatures such as pyrolysis and electron irradiation, which work with carbon sources that are easier to decompose at lower temperatures. In the case of pyrolysis, an organic compound is used, and in the case of electron irradiation, graphene is used. Certainly, the atmosphere in which the experiments are carried out plays an important role in fullerene formation to avoid undesirable reactions with other elements. To date, the formation mechanisms are not well understood, so different models that have been proposed are reviewed.

3.2.1 Fullerenes by Laser Vaporization Method

The first experiments studying vaporization of carbon clusters by a laser were carried out by *Rohlfing* et al. in 1984, revealing that only carbon clusters with an even number of atoms are formed when the number of atoms is greater than 40 [3.29].

These authors did not identify the structure of C_{60} nor of the other fullerenes. In 1985 the molecule was first identified as a very special cluster of 60 carbon atoms exhibiting the shape of a soccer ball [3.1]. This experiment consisted in using a Nd:YAG laser pulse against a graphite target under a helium atmosphere to decrease the reactivity of the carbon atoms. The molecule was detected by a mass spectrometer. It is noteworthy to say that, when the helium pressure was about 760 Torr, another strong signal corresponding to C_{70} was identified. Unfortunately, these laser experiments produced small amounts of C_{60} and other fullerenes, which prevented scientists from identifying their exact structure and physicochemical properties. Other laser experiments have also led to synthesis of

C_{60} , for example, the use of a CO_2 laser to heat benzene molecules for production of C_{60} [3.30].

3.2.2 Fullerenes by Arc Discharge

In 1990, another method to synthesize fullerenes was reported by *Krättschmer* et al. using an electric arc-discharge apparatus with graphite rods attached at both sides of the electrodes under an inert gas atmosphere to avoid reactions [3.18]. The amount of C_{60} obtained by this method was enough to dissolve it in benzene and crystallize it. Although *Krättschmer* and colleagues reported that the C_{60} crystals had hexagonal close packing, it was found that the real crystals exhibit face-centered cubic (fcc) structure. Since this method could produce high yields of C_{60} , a huge explosion of scientific articles studying its physical and chemical properties appeared. This method became the standard to produce higher fullerenes [3.24] and also carbon nanotubes [3.4].

Another high-temperature method related to arc discharge for producing C_{60} and higher fullerenes involves a hybrid plasma in which a radiofrequency plasma and a direct-current (DC) arc jet operated together can produce vaporization of carbon and the support of the hot region required [3.31].

3.2.3 Fullerenes by Pyrolysis

In the laser irradiation and arc-discharge procedures, the temperatures involved are very high, of the order of 4000 °C, so at a certain stage it becomes difficult to control or study the fullerene formation processes. Several attempts to decrease the temperature and improve control of all the parameters have been reported using lower temperatures and hydrocarbons as carbon precursors (which decompose at lower temperature than graphite). In 1993, a method for producing C_{60} and C_{70} consisting of pyrolysis of naphthalene at 1000 °C was reported [3.32]. Pyrolysis of other organic precursors such as binaphthyl and oligonaphthylene at 1100 °C has

also led to formation of C_{60} [3.33]. Synthesis of C_{60} at 700 °C by reduction of CO_2 with metallic lithium has also been achieved [3.34]. Furthermore, C_{60} , C_{70} , and higher fullerenes have been obtained by pyrolysis of defective single-walled carbon nanotubes at 1200 °C [3.35].

3.2.4 Fullerenes by Combustion in Flames

C_{60} and C_{70} can also be found in flames of hydrocarbons such as benzene in which the C_{60}/C_{70} ratio depends on the temperature, pressure, and carbon/oxygen ratio [3.36–38]. In 1997, Richter and colleagues found higher fullerenes including C_{60} and C_{70} such as C_{76} , C_{78} , C_{80} , C_{84} , C_{86} , C_{88} , C_{90} , C_{92} , C_{94} , C_{96} , C_{98} , C_{100} , C_{102} , and C_{108} in flames of benzene/oxygen/argon at pressures of around 40 Torr; These authors compared the soot of flames and that of the arc discharge and found that the abundances of higher fullerenes in the soot from flames were higher than that of the arc discharge [3.39]. It is noteworthy that flame-generated soot which contains fullerenes is formed by transformation of polycyclic aromatic hydrocarbons [3.40].

3.2.5 Fullerenes Under Electron Beam Irradiation Inside a Transmission Electron Microscope (TEM)

As we have seen in the previous synthesis methods for fullerenes, there should be a carbon source that needs to be rearranged or excited to form a metastable nanostructure such as a fullerene. Using an aberration-corrected high-resolution transmission electron microscope working at 80 keV it is possible to observe rearrangement of the carbon atoms of graphene (a single layer of graphite) to form a fullerene [3.41] (Fig. 3.6). In this case, pentagonal rings of carbon at the edges of graphene trigger the positive Gaussian curvature needed to form a ball-shaped structure, and then closure is achieved by avoidance of dangling bonds. It is not clear from this observation that the isomer formed is that of C_{60} I_h , C_{70} D_{5h} , or another fullerene. However, what is clear is that fullerenes can form under the right conditions under electron beam irradiation.

3.2.6 Fullerenes by Concentrated Solar Flux

Solar radiation can be concentrated and controlled to build furnaces which can achieve high tempera-

tures (around 3000 °C) and thereby vaporize graphite to form fullerenes [3.42, 43]. Although this method involves high temperatures as in arc discharge and laser ablation, it can be scaled to increase the yield [3.44].

3.2.7 Proposed Mechanisms for Fullerene Growth and Formation

Although there are different methods for producing fullerenes, their formation is not well understood. Although avoiding dangling bonds may be the driving force for formation of carbon cages, there remain unanswered questions regarding the formation or growth mechanisms of fullerenes. The first attempts to ex-

Fig. 3.6a–d Sequence of formation of C_{60} from graphene by electron irradiation: (a) The five–seven defects at the edges introduce the local curvature and reactivity. (b) Pentagonal and additional hexagonal rings separate from the defective graphene sheet. (c) The fullerene grows due to its reactivity (dangling bonds) by addition of carbon atoms ejected by the electron irradiation process from the graphene sheet. (d) The process is complete when the fullerene molecule closes itself, satisfying all dangling bonds

plain the formation and growth of fullerenes were the pentagon road, the fullerene road, and ring coalescence [3.45].

The Pentagon Road for Fullerene Formation

This process considers the formation of linear chains which become rings that form pentagons of carbon in the gas phase. These are responsible for the positive Gaussian curvature of the structure, forming a cup-like arrangement, until the 12 isolated pentagons are produced for the closure [3.46].

If extra pentagons (more than 12) are introduced, spirals of carbon can be formed and graphitic onions can be produced [3.47]. Different sizes of fullerenes can be formed in this way, but only those that possess isolated pentagons prevail. C_{60} I_h and C_{70} D_{5h} both exhibit isolated pentagons. This route does not take into account the possibility of generating nonclassical fullerenes [3.27].

The Fullerene Road

Heath [3.48] suggested that the formation of fullerenes in the gas phase consists of four steps:

1. Growth of carbon chains up to lengths of C_{10}
2. Growth from chains into monocyclic rings ($C_{10}-C_{20}$)
3. Production and growth of three-dimensional reactive carbon networks ($C_{20}-C_{40}$)
4. Growth of small fullerene cages (with more than 40 atoms) via closed shells in which there are adjacent pentagonal rings of carbon which constitute active

sites for addition of dimers until C_{60} and C_{70} as well as higher fullerenes are formed.

The Importance of Carbon Rings in Fullerene Formation

McElvany and colleagues used Fourier-transform mass spectrometry (FTMS) to study the reaction of cyclical carbon-oxide molecules C_{18} , C_{24} , and C_{30} , finding that these ring structures coalesce to form C_{60}^+ and C_{70}^+ [3.49]. In fact, the importance of carbon rings in the formation of fullerenes has been addressed experimentally by different groups.

Von Helden and coworkers showed experimentally that fullerenes can be formed in the gas phase by a three-stage process: from linear chains of carbon atoms to planar rings and then to fullerenes accompanied by evaporation of small carbon fragments C_1 or C_3 for odd systems and C_2 for even systems [3.50]. *Hunter* and coworkers studied the annealing of nonfullerene C_{60}^+ cluster ions, finding that these, when fragmented, form C_{60} fullerenes and monocyclic rings. These rings are very stable and constitute another nonspheroidal form of carbon [3.51]. *Pope* et al. proposed a mechanism which uses polycyclic aromatic hydrocarbons to form C_{60} and C_{70} in flames [3.52].

Some theoretical models involve carbon dimer additions to small nonclassical fullerenes during a very fast reaction at high temperature in arc-discharge synthesis [3.27]. It is noteworthy that closed cages of fullerenes, both classical and nonclassical, should have an even number of carbon atoms, more than 20 (with the exception of 22).

3.3 Physicochemical Properties of Fullerenes

Working with fullerenes involves studying their crystals, known as fullerites, and obviously the molecules themselves. In this section the physical properties reviewed are those of the fullerites, studying their structure, different phases, and electronic behavior. Regarding their chemical properties, isolated fullerene molecules interact with other elements or compounds, forming new ones which might have important applications in the future.

3.3.1 Mechanical Properties and Phases of Fullerene Crystals

Fullerites are formed by crystallization of fullerenes. As we have seen, *Krätchmer* and colleagues in their

original paper reported that C_{60} crystals, under normal conditions, exhibited hexagonal close-packing (hcp) structure [3.18]; however, the actual packing of fullerite (crystals of C_{60}) is face-centered cubic (fcc) with cell parameter of 14.198 Å, and the molecules exhibit orientational disorder [3.53]. When the temperature is decreased to 294 K, the C_{60} molecules become ordered (no rotation) and the fcc phase changes to a simple cubic (SC) phase [3.53].

C_{60} fullerite is stable at hydrostatic pressures of 20 GPa, but when the pressure is nonhydrostatic, changes are produced, lowering the symmetry of C_{60} crystals [3.54]. *Regueiro* and colleagues found that nonhydrostatic pressure on fullerite can lead to polycrystalline diamond at room temperature [3.55]. Fullerite is

a semiconductor with band gap of 1.5 eV [3.56], and although pressure induces changes in the gap of fullerite, a metallic phase is not observed [3.57]. At pressures of the order of 5 GPa and temperatures of 400 °C, a new fcc phase is observed. Increasing the temperature to 800 °C, a rhombohedral phase is found [3.58]. The compression behavior of fullerite and its phase diagram have been discussed in detail by *Sundqvist* [3.59]. C₇₀ also possesses different phases such as fcc, hcp, and monoclinic [3.60]. Certainly, investigation in crystals obtained from other fullerenes, considering doping, should continue to identify new applications, possibly in electronics.

3.3.2 Electrical Properties and Superconductivity of Fullerites

Despite the semiconducting nature of fullerite crystals with band gap around 1.5 eV [3.56, 61], films of C₆₀ and C₇₀ doped with alkali metals (Rb, K, or Cs) are conducting [3.62]. In the AC₆₀ fullerite phases, where A is Rb, K, or Cs, linkage due to [2 + 2] cycloaddition between the C₆₀ molecules is observed, causing a 9% reduction of the cell parameters in one direction and thus resulting in polymerization of the C₆₀ molecules in one direction [3.63, 64].

However, superconductivity has been observed at low temperatures. C₆₀ fullerite doped with potassium atoms exhibits a superconducting temperature of 18 K [3.65]. According to Rietveld analysis of x-ray diffraction data, the superconducting phase K₃C₆₀ corresponds to a fcc lattice with potassium atoms occupying interstitial sites [3.66].

The superconducting temperature can be increased to 28 K when using Rb [3.67] and up to 33 K when using cesium and rubidium together [3.68]. The electronic structure, conductivity, and superconductivity of alkali metal-doped C₆₀ have been studied and reviewed thoroughly by *Haddon* [3.69]. To explain the superconductivity in fulleride systems (fullerite crystals doped with metal atoms) the electron–phonon coupling has been studied theoretically [3.70]. Superconductivity at 8.4 K of C₆₀ doped with calcium has also been reported [3.71]. Cesium-doped fullerenes can reach superconducting temperatures of up to 40 K [3.72, 73].

In 2010, *Ganin* and coworkers isolated a phase of a Cs₃C₆₀ crystal which shows magnetic semiconduct-

ing behavior at ambient pressure and superconducting behavior under pressure [3.74].

3.3.3 Chemical Properties of Fullerenes

C₆₀ and higher fullerenes have opened a new chemistry in which the fullerenes behave as a superatom. In the early stages of fullerene research, *Taylor* and *Walton* recognized the importance of C₆₀ and C₇₀ as reactive species that can undergo several chemical reactions [3.75]. In C₆₀ there is an alternation of bonds, which plays an important role in chemical reactions: There are 30 (6–6) bonds at the junctions between two six-member rings with bond length of ca. 1.38 Å. These bonds have a double-bond character. On the other hand, there are 60 bonds between adjacent pentagons and hexagons (6–5) with length around 1.45 Å. The introduction of one double bond between a hexagon and a pentagon costs energy (around 8.5 kcal/mol) [3.76, 77]. Therefore, through these double bonds, C₆₀ can interact with other atoms or molecules. Early electrochemical experiments showed that oxidation of C₆₀ and C₇₀ is difficult to achieve, but they can be reduced with multiple one-electron reduction steps [3.78]. Via Birch reduction, C₆₀ can be hydrogenated to obtain C₆₀H₃₆ [3.79].

Suzuki and coworkers were able to add phenol groups to C₆₀ to form fulleroids C₆₁ and C₆₆ [3.80]. Different groups have made important contributions in the study of cycloaddition reactions of C₆₀ [3.81–84].

The reactivity of C₆₀, as described by *Diederich* and *Thilgen*, consists of a strained electron-deficient polyalkene with localized double bonds [3.77]. C₆₀ reacts with transition metals such as iridium, ruthenium, osmium, rhenium, palladium, and platinum through these double bonds [3.85, 86]. Halogenation reactions with fluorine, chlorine, and bromine have also been achieved [3.86].

The basics of C₆₀ chemistry with applications in materials science have been studied and reviewed by *Prato* [3.87]. Among these applications of C₆₀ are the incorporation of C₆₀ into polymers for photoconductive devices, thin films with C₆₀, and electrooptical devices. It is no exaggeration to say that fullerenes have their own chemistry which certainly will find a future in different applications such as health and energy.

3.4 Applications of Fullerenes and Beyond

One of the expectations of nanotechnology is to help in solving problems related to health, energy, and the environment. In this context, fullerene researchers have made important contributions that show the potential of these amazing molecules. In this section, some of the most relevant advances are presented. In addition, it is fair to say that fullerenes have also opened other fundamental research areas with related materials such as carbon onions, which consist of nested fullerenes, fullerene peapods, high-genus fullerenes, inorganic fullerenes made of metal chalcogenides, and nanodiamonds. The potential of these nanostructures is discussed in the next sections.

3.4.1 Fullerenes and Health

As a multidisciplinary activity, one of the aims of nanoscience and nanotechnology is to help in solving some human health problems. Since 1993, extensive research has been carried out on use of C_{60} as a virucidal compound to inhibit human immunodeficiency virus (HIV) enzymes [3.88–90].

In vivo experiments in rats have been carried out with water-soluble fullerenes, showing that they are not acutely toxic. Fullerenes distribute rapidly in many tissues and thus may be useful for drug delivery applications [3.91]. Research into functionalized fullerenes in water has led to important achievements such as the interaction of organofullerenes with DNA, proteins, and living cells, their photochemical properties, radical quenching, and hydrophobicity [3.92].

Among the applications that fullerene derivatives might have in biological systems are as antioxidants and neuroprotective agents, antiapoptotic activity, DNA photocleavage, enzyme inhibition, antimicrobial activity, osteoporosis therapy, antifullerene monoclonal antibodies, contrast agents and radiotracers, and gene transfection agents [3.93]. Also, fullerenes might help in inhibiting allergic responses [3.94].

Cytotoxic mechanisms of C_{60} and its derivatives have also been studied in detail [3.95,96].

3.4.2 Fullerenes in Solar Cells

An important advancement in solar cell design has been made using the bulk heterojunction approach in which a donor-type conjugated polymer is blended with an acceptor fullerene. In this context, highly soluble fullerene derivatives such as methanofullerene

[6,6]-phenyl C_{61} -butyric acidmethyl ester, a new azafulleroid, and a ketolactam quasifullerene have been synthesized for use as electron acceptors in plastic solar cells. It has been found that the open-circuit voltage in the solar cells is directly related to the acceptor strength of the fullerenes [3.97], so plastic solar cells including fullerenes might have a future as new solar cell devices [3.98]. Wienk et al. have shown that methano[70]fullerene, based on C_{70} fullerenes, can be used in plastic solar cells with power conversion efficiency (PCE) of 3% [3.99]. Photovoltaic solar cells with PCE of 1.45% have been also obtained using a mixture of porphyrin nanoclusters with C_{60} and gold nanoparticles [3.100]. Imahori and Fukuzumi used just porphyrins and C_{60} to produce a photovoltaic cell with PCE of 1% [3.101]. Endohedral fullerenes such as trimetallic nitride inside the C_{80} I_h fullerene, $Lu_3N@C_{80}$, have been used in polymer solar cells as an electron acceptor with PCE of more than 4% [3.102]. The performance of inverted solar cells using ZnO nanoparticles as the electron selective layer can be improved from 3.7% to 4.5% after modification with a C_{60} self-assembled monolayer [3.103]. Troshin et al., prepared 27 derivatives of C_{60} and C_{70} for use in plastic solar cells, finding that the PCE varies from as little as (0.02%) to considerably high (4.1%) [3.104]. Use of alkene dithiols in semiconducting polymer solar cells with C_{60} derivatives increases the PCE from 2.8% to 5.5% [3.105]. Solar cells based on semiconducting polymers and C_{60} fullerene derivatives (tandem solar cells) can achieve PCE of the order of 6.7% [3.106].

Hatakeyama and colleagues used fullerene C_{60} inside single-walled carbon nanotubes (fullerene peapods) to increase the efficiency of infrared photovoltaic solar cells [3.107]. Polymer photodetectors made with polymers and C_{60} derivatives exhibit spectral responses from 300 up to 1350 nm and can substitute photodetectors based on inorganic materials [3.108].

3.4.3 Nested Fullerenes: Carbon Onions

As a byproduct of electric arc-discharge experiments, it is common to find, besides carbon nanotubes and C_{60} , polyhedral particles of carbon which look like nested or matryoshka-like fullerenes formed by giant fullerenes one inside the other (Figs. 3.7, 3.8). In 1980, Iijima reported high-resolution TEM studies of nested carbon structures [3.109] and in 1987 recognized the possi-

bility of having C_{60} in the most interior shell of these onions [3.110].

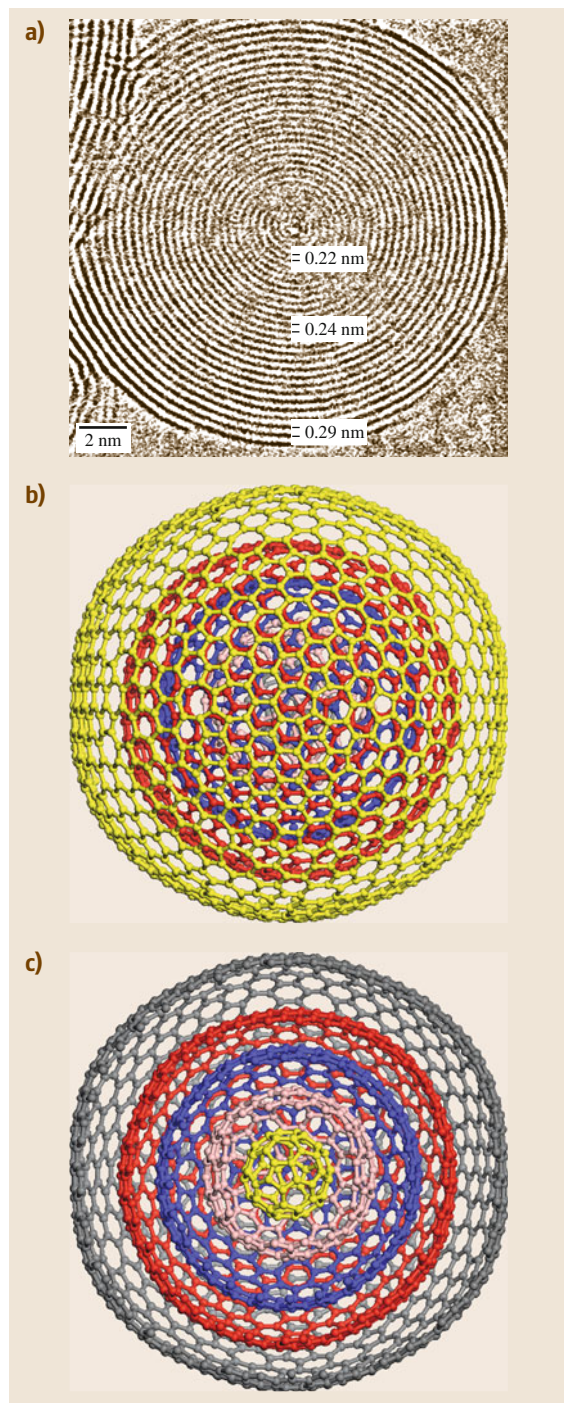

Fig. 3.7a–c Giant icosahedral (I_h) fullerenes: (a) C_{540} , (b) C_{960} , and (c) C_{1500}

Ugarte found that, by irradiating amorphous carbon with the electron beam of a transmission electron microscope, quasispherical carbon onions were produced in situ [3.7, 112, 113]. The high sphericity attracted the attention of researchers, since in most cases, polyhedral graphitic particles exhibit facets. A model which explained the sphericity of carbon onions through the introduction of pentagonal and heptagonal rings of carbon was proposed by Terrones et al. (Fig. 3.8) [3.114–116]. These spherical onions compete in terms of stability with classical fullerenes [3.117].

Another important observation of spherical carbon onions consisted in the formation of diamond inside

Fig. 3.8 (a) Carbon onion obtained by electron irradiation and heating. The graphitic distances inside the onion are shorter than outside due to pressure effects (after [3.111], courtesy of Elsevier). (b) Model of a carbon onion in which the sphericity of the nanostructure is obtained by the addition of heptagon–pentagon pairs of carbon: the Terrones model. (c) Cut of the onion shown in (c) depicting the several nested fullerenes ◀

Fig. 3.9 (a) Carbon onion with diamond grown at the center (after [3.118]). (b) Model of a two-shell carbon onion with diamond inside. (c) Simulation of a high-resolution TEM image of the onion shown in (b), in which the diamond lattice can be resolved ►

them under transmission electron microscope action (Fig. 3.9). Therefore, it is possible to grow nanodiamond inside carbon onions. The pressure inside carbon onions and electron irradiation help the diamond formation. In Fig. 3.9b,c a molecular model of a carbon onion with diamond inside and a high-resolution image simulation are shown [3.111, 118, 119].

Although these higher nested fullerenes require more study, important advances have been reported. Recently, it was found that carbon onions exhibit excellent properties as supercapacitors [3.120].

Chemical vapor deposition processes at temperatures between 750 °C and 850 °C have also been used to produce considerable amounts of carbon onions with diameters of 400–2000 nm [3.121–124].

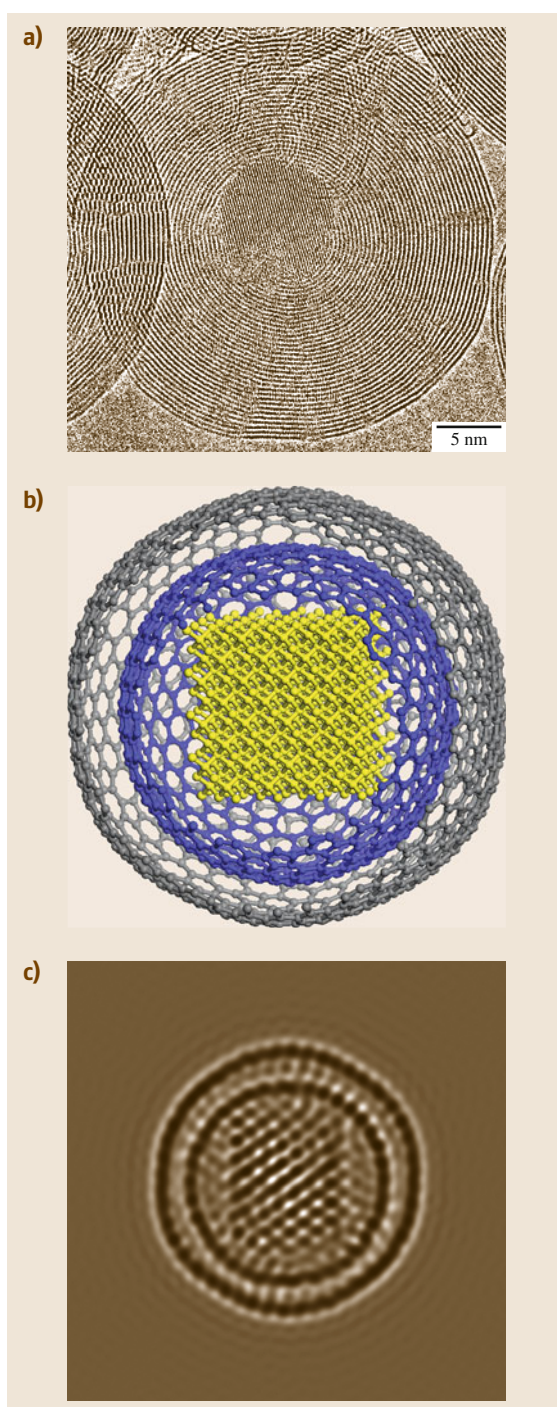

Other applications of carbon onions include: Use as x-ray target materials prepared with lanthanum carbide and lanthanum hexaboride [3.125], for electrodes in Li-ion batteries [3.126] and broadband wave absorbers in the GHz and THz regions [3.127]. When filled with nickel, using the electric arc-discharge technique, good electromagnetic absorbers in the 2–18 GHz range can be obtained [3.128].

A new electron field emitter has been produced by attaching a single carbon onion to the tip of a tungsten nanowire. This new kind of emitter can sustain large emission currents of more than 100 μ A and possesses long-term emission stability [3.129].

In the biological area, the toxicity of carbon onions used as contrast agents when filled with lanthanide carbides has been assessed, showing that it is similar to or lower than that of TiO₂ nanoparticles [3.130]. Gold nanoparticles attached to carbon onions could be used for immobilizing biomolecules or as biomolecule sensors [3.131]. Iron–cobalt nanoparticles inside carbon shells have been made soluble in water and tested in magnetic resonance imaging in rabbits, with applications also in photothermal treatment using magnetic fields [3.132].

3.4.4 Fullerene Peapods and Fullerene Coalescence

It has been found that, during the laser evaporation process to form single-walled carbon nanotubes, C₆₀

can also be generated and introduced inside single-walled carbon nanotubes, thus forming a nanopeapod

Fig. 3.10 (a) Carbon nanotubes with C_{60} inside fullerene peapods. (b) Cut of a carbon nanotube showing the C_{60} molecules inside ►

(Fig. 3.10) [3.133–136]. Luzzi and Smith proposed that C_{60} accumulates on the surface of the nanotubes and enters via defects, forming linear van der Waals chains of molecules, which can coalesce to create an inner tube (Figs. 3.11, 3.12) [3.136].

Evidence of coalescence reactions in C_{60} and C_{70} has been reported by Yeretzian and coworkers [3.138]. Coalescence of C_{60} with negative Gaussian curvature, preserving the sp^2 bonding, has been used to propose theoretical models of icosahedral aperiodic arrangements in 3-D [3.139].

Scanning tunneling microscopy (STM) and scanning tunneling spectroscopy (STS) have revealed electronic modulation effects due to the chain arrangement of C_{60} molecules inside single-walled carbon nanotubes (SWCNT) [3.140]. High yields of fullerene peapods can be generated by sublimation methods, including the introduction of C_{70} molecules [3.141, 142]. Raman spectroscopy has been used to study the fullerene coalescence process inside a SWCNT, proposing that the coalescence leads to zigzag inner nanotube formation [3.143].

Theoretical studies have shown that, depending on the C_{60} orientation of the molecules (inside the nanotubes), the inner tube can be metallic or semiconducting [3.137]. The electrochemical properties of fullerene peapods are dominated by their capacitive charging, without any distinct Faradaic processes, and is similar to that of empty single-walled carbon nanotubes [3.144]. Gadolinium metallofullerene $Gd@C_{82}$ has been synthesized by arc discharge and introduced inside SWCNTs using a sealed glass ampule at 500 °C, thus produc-

Fig. 3.11a–h Sequence of TEM micrographs showing irradiation-induced coalescence of C_{60} within the lumen of an isolated SWNT. (a) Starting configuration after a minimal electron dose. (b–h) Consecutive images recorded at 60–90 s intervals. Damage to the fullerenes occurs by knock-on ejection of carbon atoms, resulting in structural reconfiguration into corrugated tubules that are ca. 5–7 Å in diameter. These tubules exhibit regions of negative curvature that may be associated with the formation of heptagonal rings acting to link the discrete molecules together. Pronounced damage to the SWNT is also visible beginning in (c), but its damage rate is appreciably slower because of curvature effects. Therefore, C_{60} – C_{60} fusion predominates over C_{60} –SWNT fusion (after [3.137], courtesy of ACS) ►

ing a metallofullerene one-dimensional crystal inside SWCNTs in which the Gd atom might transfer charge to the fullerene and to the SWCNT [3.145]. A metallofullerene is a fullerene which encapsulates a metal atom.

Praseodymium and scandium atoms inside C_{80} ($PrSc@C_{80}$) have been encapsulated inside a SWCNT and identified using electron microscopy techniques

Fig. 3.15 Boron nitride cage $B_{64}N_{64}$ with T_d symmetry

3.4.5 High-Genus Fullerenes

As has been seen in the previous section, fullerenes can coalesce and form one-dimensional (1-D) chains or nanotubes; however, another possibility is formation of toroidal structures (Fig. 3.13), which can respond to a magnetic field, exhibiting an induced magnetic moment, depending on the orientation of the C_{60} molecules [3.147]. For the case of coalesced toroidal C_{60} molecules the genus g is 1, the same as for a donut.

More complex architectures can be proposed by coalescing larger fullerenes, starting from onion-like structures; for example, a genus-11 holey fullerene with I_h symmetry can be constructed by coalescing a I_h C_{500} and a I_h C_{240} fullerene [3.148] (Fig. 3.14). Closed nanotubes up to genus 21 have been proposed [3.148]. Using a tight-binding approach, the electronic properties of these complex fullerenes can be calculated, finding that their holes behave as active sites for attachment of molecules or foreign atoms [3.149], which can be used as molecular sensors or for hydrogen storage [3.150]. Different families of high-genus fullerenes have been proposed and classified according to their geometrical features [3.151].

3.4.6 Inorganic Fullerenes (BN, MoS_2 , NbS_2 , etc.)

Graphite and graphene are not the only layered materials; there are others such as boron nitride (BN)

and molybdenum, tungsten, and rhenium disulfides. Hexagonal BN is composed of hexagonal flat layers with hexagonal rings of alternating boron and nitrogen atoms. In the case of BN fullerenes, six squares are required to close the structure and preserve the stoichiometry (Fig. 3.15). Octahedral BN nested fullerenes (up to three layers) have been found by electron irradiation [3.152].

Theoretical calculations have been performed on octahedral BN fullerenes [3.153]. Closed-tip boron nitride nanotubes have been found in electric-arc discharge made out of BN inside tantalum rods [3.154] and tungsten rods [3.9]. The tip of these tubes might exhibit half

Fig. 3.16 (a) Molybdenum sulfide cage $Mo_{64}S_{128}$ with T_d symmetry. (b) Stoichiometry-preserving defects in metal chalcogenide layers: square-like defect responsible for the positive Gaussian curvature. (c) Octagonal-like defect responsible for the negative Gaussian curvature (*smaller atoms* are the metal atoms)

Fig. 3.17 Tungsten sulfide WS_2 (18,18) armchair nanotube

a BN fullerene [3.155]. Pentagonal rings can be stable in BN fullerenes if there is a nitrogen excess [3.155].

Tenne and coworkers found that metal chalcogenides can acquire curvature to form fullerene-like structures and nanotubes [3.12] (Figs. 3.16, 3.17). In fact, WS_2 fullerenes can be used as solid lubricants [3.156]. The curvature in these systems requires a square-like defect for positive Gaussian curvature and an octagon-like defect for negative Gaussian curvature [3.157]. These fullerene-like structures could exhibit octahedral symmetry (T_d point group) and possess six square-like defects (Fig. 3.16).

3.4.7 Nanodiamond

Nanodiamonds are small clusters of sp^3 carbon in which each atom is connected covalently to four nearest neighbors, except for the boundary atoms. It has been shown in this chapter that fullerite under high pressure and high temperature becomes diamond and also that carbon anions undergo a phase transformation into diamond [3.158]. Following Shenderova et al., there are two large groups of nanodiamond: The first group involves nanodiamonds as a final product obtained from methods such as electron irradiation of carbon anions, ultrananocrystalline diamond films, and ultradispersed diamond obtained from detonation synthesis [3.159]; The other group involves nanodiamonds which are the result of interrupting the process of growth of micro- or macrodiamonds [3.158]. It is worth mentioning that there is diamond in interstellar space found in meteorites [3.159, 160]. Approximately 10–20% of interstellar carbon is in the form of nanodiamonds.

The fluorescence properties of nanodiamonds enable their use as biological markers, which might have application in the future for tumor targeting [3.161]. In

Fig. 3.18 Nanodiamond saturated with hydrogen

this context, it has been found that nanodiamonds of sizes between 2 and 10 nm are not toxic [3.162].

First-principles calculations indicate that the nanodiamond surface can be reconstructed by sp^2 bonding, forming a kind of hybrid between a fullerene and diamond, having diamond in the interior and a fullerene on the surface [3.163].

Diamonoids are a variant of carbon cage molecules made of sp^3 carbon saturated with hydrogen (Fig. 3.18). Among these molecules are: adamantane ($\text{C}_{10}\text{H}_{16}$), iceane ($\text{C}_{12}\text{H}_{18}$), diamantane ($\text{C}_{14}\text{H}_{20}$), triamantane ($\text{C}_{18}\text{H}_{20}$), pentamantane ($\text{C}_{25}\text{H}_{30}$), and superadamantane ($\text{C}_{35}\text{H}_{36}$). Larger diamonoids have been isolated from petroleum and might have applications in biology as well as electronics and field emission [3.164].

3.5 Conclusions

Buckminsterfullerene opened the field of carbon nanostructures, strengthened nanoscience and nanotechnology, and brought about a new way of doing science involving multidisciplinary. The whole spectrum of new applications for layered nanomaterials is very promising, and certainly the novel building blocks for advanced materials in the 21st century will include fullerenes, carbon nanotubes, graphene, graphene nanoribbons, carbon onions, porous carbons, boron nitride nanoribbons, and metal chalcogenide nanostructures. The idea of producing, out of any bulk

material, a thin layer, one atom thick, and curving it in different ways, opens new avenues in advanced architectures. New characterization techniques and new tools will have to be developed to make full use of them.

These nanomaterials will play an essential role in the immediate challenges such as efficient energy production, environmental remediation, and health problems. It is no coincidence that two carbon nanostructures, C_{60} and graphene, have been awarded two Nobel Prizes in two different fields.

Single-Walled Carbon Nanotubes

Sebastien Nanot, Nicholas A. Thompson, Ji-Hee Kim, Xuan Wang, William D. Rice, Erik H. H  roz, Yogeewaran Ganesan, Cary L. Pint, Junichiro Kono

Single-walled carbon nanotubes (SWCNTs) are hollow, long cylinders with extremely large aspect ratios, made of one atomic sheet of carbon atoms in a honeycomb lattice. They possess extraordinary thermal, mechanical, and electrical properties and are considered as one of the most promising nanomaterials for applications and basic research. This chapter describes the structural, electronic, vibrational, optical, transport, mechanical, and thermal properties of these unusual one-dimensional (1-D) nanomaterials. The crystallographic (Sect. 4.2.1), electronic (Sect. 4.2.2), vibrational (Sect. 4.2.3), optical (Sect. 4.4), transport (Sect. 4.5), thermal (Sect. 4.6.1), and mechanical (Sect. 4.6.2) properties of these unusual 1-D nanomaterials will be outlined. In addition, we will provide an overview of the various methods developed for synthesizing SWCNTs in Sect. 4.3.

Even after more than two decades of extensive basic studies since their discovery, carbon nanotubes continue to surprise researchers with potential new applications and interesting discoveries of novel phenomena and properties. Because of an enormous thrust towards finding practical applications, carbon nanotube research is actively being pursued in diverse areas including energy storage, molecular electronics, nanomechanical devices, composites, and chemical and bio-sensing.

Structurally, carbon nanotubes are made up of sp^2 -bonded carbon atoms, like graphite, and can be conceptually viewed as rolled-up sheets of single-layer graphite, or graphene. Their diameter typically lies in the nanometer range while their length often exceeds microns, sometimes centimeters, thus making them 1-D nanostructures. Depending on the number of tubes that are arranged concentrically, carbon nanotubes are further classified into single-walled and multi-

walled nanotubes. Single-walled carbon nanotubes, the subject of this chapter, are especially interesting. They are ideal materials in which to explore one-dimensional physics and strong Coulomb correlations. In addition, their cylindrical topology allows them to exhibit nonintuitive quantum phenomena when placed in a parallel magnetic field, due to the Aharonov-Bohm effect. A number of research groups have found exotic many-body effects through a variety of transport, optical, magnetic, and photoemission experiments.

Their electronic properties are very sensitive to their microscopic atomic arrangements and symmetry, covering a wide spectrum of energy scales. They can be either metallic or semiconducting with varying band gaps, depending on their diameter and chirality. Semiconducting nanotubes are particularly promising for photonic device applications with their diameter-dependent, direct band gaps, while metallic tubes are considered to be ideal candidates for a variety of electronic applications such as nanocircuit components and power transmission cables.

4.1 History

This chapter summarizes some of the basic properties of carbon nanotubes (CNTs), one of the most ideal realizations of one-dimensional (1-D) systems available today. Since their discovery [4.1], much attention has been given to their unique structure and properties that are promising for a wide range of applications and fundamental physical and chemical studies [4.2–5]. These hollow crystals of sp²-bonded carbon atoms have exhibited a variety of extraordinary thermal, mechanical, and electrical properties and phenomena, fascinating scientists and engineers in diverse disciplines. Even after more than two decades of extensive basic studies since their discovery, they continue to surprise researchers through exciting discoveries of phenomena and properties as well as novel potential applications, including energy storage, molecular electronics, nanomechanical devices, composites, and chemical and bio-sensing.

The diameters of carbon nanotubes are in the nanometer range while their lengths are typically microns and often millimeters, corresponding to aspect ratios of millions, especially in single-walled carbon nanotubes (SWCNTs), the most prominent member of the carbon nanotube family. A typical SWCNT has a diameter of ≈ 1 nm and consists of just one atomic sheet, which can be pictured as a rolled-up version

of graphene, i.e., a honey-comb lattice of sp²-bonded carbon atoms. The one-dimensionality of SWCNTs is attractive, allowing researchers to explore exotic 1-D physics in the quantum regime [4.6] and new functionalities in optoelectronic devices [4.7, 8]. The strong 1-D confinement of electrons and phonons results in unique anisotropic effects in various properties, e.g., polarization-dependent Raman scattering [4.9] and optical absorption [4.10–12], large magnetic susceptibility anisotropies [4.13–17], and anisotropic terahertz dynamic conductivities [4.18–21].

One of the most striking properties of SWCNTs is their chirality-dependent metallicity. Namely, depending on their microscopic atomic arrangements and symmetry, a SWCNT can be either metallic or semiconducting. A subtle structural difference leads to opening or closing of a band gap, which is also tunable by a magnetic field applied parallel to the tube axis via the Aharonov–Bohm effect [4.10, 22–25]. Semiconducting nanotubes are particularly promising for photonic device applications with their diameter-dependent, direct band gaps, while metallic tubes are considered to be ideal candidates for a variety of electronic and electrical applications ranging from nano-circuit wires to power transmission cables.

4.2 Crystallographic and Electronic Structure

A SWCNT can be viewed as a graphene sheet rolled into a cylinder which is terminated by two half-fullerene caps. The diameter of these species typically ranges from 0.7 to 2.5 nm, and their aspect ratio can be as high as 10⁴–10⁵. This very strong confinement along their circumference make them behave like 1-D materials. The purpose of this section is to describe the crystallographic and electronic structure of SWCNTs, which will be used throughout the text. For a more detailed

study we refer the reader to some of the many published books [4.2, 5, 26–28].

4.2.1 Crystallographic Structure

To give a formal description of the crystal structure of a SWCNT, it is easiest to first consider its parent material, graphene. Graphene is a monolayer of sp²-hybridized carbon atoms arranged in a honeycomb

lattice. Its unit cell is defined by the primitive vectors \mathbf{a}_1 and \mathbf{a}_2 (bottom right of Fig. 4.1, for a review see [4.29]). Each SWCNT is then indicated by a *chiral vector* \mathbf{C}_h , which specifies the two atoms of the graphene sheet which are identified upon formation of the tube (see the points O and A in Fig. 4.1). The chiral vector is defined with respect to the graphene primitive vectors as

$$\mathbf{C}_h \equiv n\mathbf{a}_1 + m\mathbf{a}_2 \equiv (n, m), \quad (4.1)$$

where n and m are integers such that $0 \leq m \leq n$. When we express the chiral vector \mathbf{C}_h in the form (n, m) , we call it the *chiral index*. These two terms should be regarded as synonymous. The angle θ formed between \mathbf{C}_h and \mathbf{a}_1 is a quantity of great importance for determining the electronic properties of the SWCNT; it is called the *chiral angle*, and is defined through

$$\cos \theta = \frac{\mathbf{C}_h \cdot \mathbf{a}_1}{|\mathbf{C}_h| |\mathbf{a}_1|} = \frac{2n + m}{2\sqrt{n^2 + m^2 + nm}}. \quad (4.2)$$

The nanotube diameter can be computed from the chiral vector by

$$d_t = |\mathbf{C}_h| / \pi = \frac{a_{C-C}}{\pi} \sqrt{3(m^2 + mn + n^2)}, \quad (4.3)$$

where $a_{C-C} \approx 1.44 \text{ \AA}$ is the nearest neighbor distance between carbon atoms in graphene.

SWCNTs can be classified into three main types:

1. *Armchair* nanotubes for which $n = m$ (i.e. $\mathbf{C}_h = (n, n)$)
2. *Zig-zag* nanotubes for which $m = 0$ (i.e. $\mathbf{C}_h = (n, 0)$)
3. *Chiral* nanotubes ($n \neq m \neq 0$) whose mirror images have a different structure and display different properties, for example in circular dichroism.

Armchair and zigzag nanotubes (having the highest symmetry) (Fig. 4.1b) are named after the shape of their cross section along \mathbf{C}_h . All three of these different structures will display various physical properties and their distinction will be of prime importance for their electronic structure, phonon dispersion and optical properties.

4.2.2 Electronic Dispersion

Single-walled carbon nanotubes can be either metals or semiconductors depending on their chirality (Sect. 4.2.1). Their metallicity can be deduced from purely geometrical considerations related to their chiral angle. Similar conclusions can be drawn from

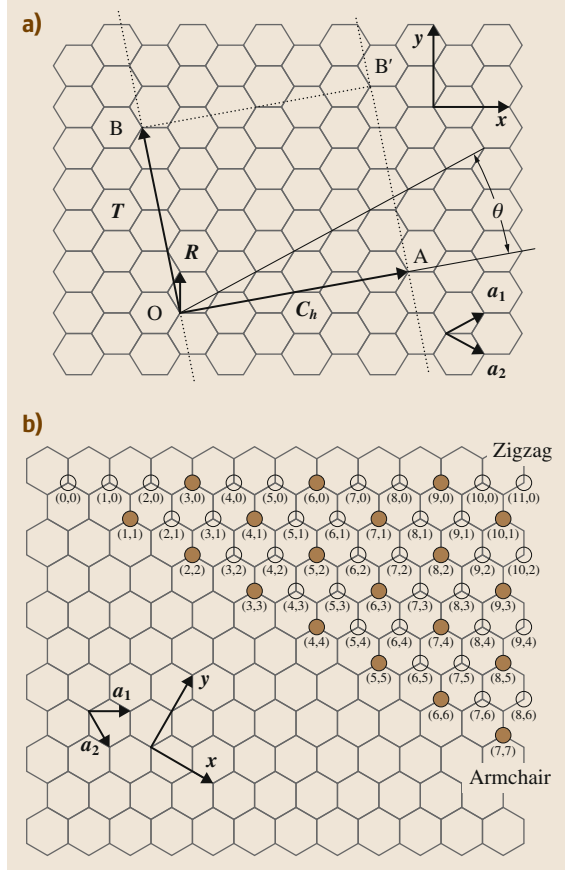

Fig. 4.1 (a) The unrolled hexagonal lattice of a nanotube. When we connect sites O–A, and B–B', a nanotube can be constructed. \mathbf{OA} and \mathbf{OB} define the chiral vector \mathbf{C}_h and the translational vector \mathbf{T} of the nanotube, respectively. The rectangle OAB'B defines the unit cell for the nanotube. The vector \mathbf{R} denotes a symmetry vector. (b) The hexagonal lattice of all possible (n, m) species formed by rolling the $(0, 0)$ point onto (n, m) . The empty circles are semiconducting (n, m) , ($v = \pm 1$). The filled circles represent *metallic*, $v = 0$ (n, m) species. (After [4.26])

tight-binding models of graphene [4.30, 31] or $\mathbf{k} \cdot \mathbf{p}$ formalism for low energy bands [4.32], although the precise band structure of (very) small diameter nanotubes necessitates more complex calculations which include curvature effects, second neighbor interactions, or the use of ab initio methods [4.33].

The electronic properties of graphene have been studied extensively [4.29], so here we will only describe the properties useful for deducing the nanotube band structure. The graphene reciprocal lattice is hexagonal

Fig. 4.2a,b First Brillouin zone and quantized vectors of (a) an armchair nanotube (5,5) and (b) a zigzag nanotube (8,0) with rotational indices q corresponding to the zone folding method indices. PZB = 1st Brillouin zone (After [4.35])

and the (nonequivalent) points K and K' at the corners of the first Brillouin zone (called *Dirac points*) are of particular importance for its electronic properties. The valence and conduction band meet only at the Dirac points [4.34], making graphene a zero bandgap semiconductor. Moreover, its dispersion is linear close to these points and hence low energy carriers behave like massless, chiral Dirac fermions. As a consequence, its electronic dispersion near the Dirac points is well described by

$$E(\delta k) = \pm \hbar v_F \delta k, \quad (4.4)$$

where $v_F = \sqrt{3}\gamma_0 a / 2\hbar \approx 9.5 \times 10^5$ m/s is the electron Fermi velocity, $\gamma_0 = 2.9$ eV is the nearest neighbor hopping energy, $a = |\mathbf{a}_1| = |\mathbf{a}_2| = 2.49$ Å and δk is the wavevector with origin at either the K or K' point.

The periodicity condition introduced on the wavefunctions along the circumference of carbon nanotubes induces a quantization along their axes. As a consequence, they are quasi-1-D systems with only specific \mathbf{k} vectors allowed along the circumference and the base vector parallel to the axis, as illustrated in Fig. 4.2. The mono-electronic dispersion relation can be directly deduced from graphene by using the *zone folding method*, which imposes the periodic boundary condition $\psi(x + nC_h) = \psi(x)$ on graphene. The continuous graphene wavevector is replaced by a *half-quantized* new vector (continuous along the nanotube axis and quantized along the circumference). As can be seen from Fig. 4.2, a specific (n, m) nanotube will be metallic if an authorized subband crosses the K point or semiconducting otherwise. Simple geometric considerations related the chiral vector C_h allows one to deduce

that the condition for a nanotube to be metallic is $n - m = 3\ell$ ($\ell \in \mathbb{N}$) [4.30, 31, 33]. If we define $\nu \equiv n - m \bmod 3$, we can see that $\nu = 0$ if the nanotube is metallic and $\nu = \pm 1$ if it is a semiconductor. Hence one-third of all possible carbon nanotube species are expected to be metallic.

Using (4.4), one can deduce the band structures close to the K points through the $\mathbf{k} \cdot \mathbf{p}$ formalism [4.32]

$$E_q(k) = \pm \gamma_0 \sqrt{\left(q - \frac{\nu}{3}\right)^2 + \left(\frac{kd_t}{2}\right)^2}. \quad (4.5)$$

Noticeably:

- Metallic nanotubes have a linear dispersion and massless charge carriers, just as their parent material graphene
- Semiconducting nanotubes have a band gap $E_g = 2\gamma_0 a_{C-C} / d_t \approx 0.839$ eV · nm / d_t .

A complete band structure can be deduced by folding the tight-binding dispersion of graphene [4.30, 31, 33]. This is shown for a representative metallic armchair nanotube and a semiconducting zigzag nanotube of similar diameters in Fig. 4.3. Due to symmetries of the K and K' points, all subbands are doubly degenerate. The corresponding density of states (Fig. 4.4) is constant in the metallic bands and presents van Hove singularities typical of 1-D systems at the onset of each new subband.

These considerations are sufficient for nanotubes with large diameter. However, for small diameter nanotubes, one has to consider the distortions of the

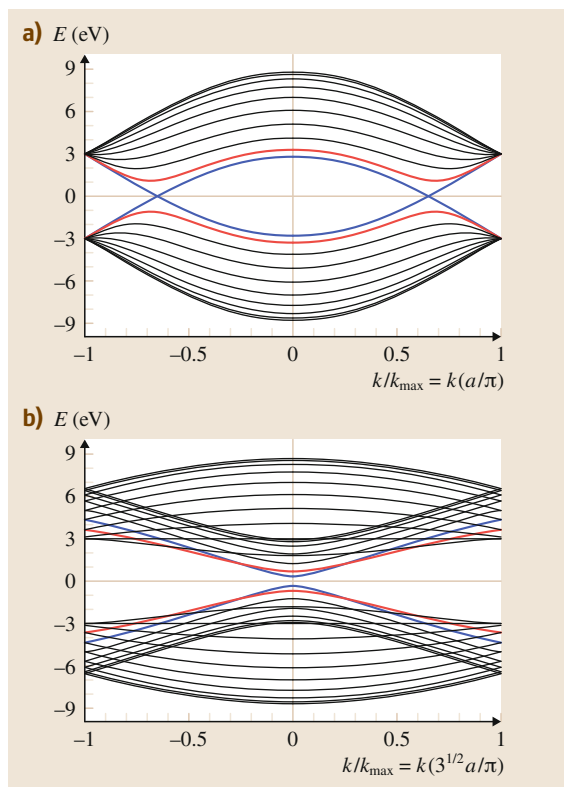

Fig. 4.3a,b Electronic dispersion of (a) a metallic (9,9) armchair nanotube and (b) a semiconducting (16,0) zigzag nanotube. Both nanotubes have similar diameter $d_t \approx 1.2$ nm

Fig. 4.4 Density of states (DOS) of the same SWCNTs as above; a metallic (9,9) armchair nanotube (black curve) and a semiconducting (16,0) zigzag nanotube (dark-brown curve)

hexagonal lattice due to curvature [4.31, 36] and that graphene dispersion is not linear at the high energies where new subbands appear (i. e., (4.4) and (4.5) are no longer valid, due to trigonal warping effects). These become of particular importance for optical experiments and low temperature transport measurements. Important considerations are:

- Armchair (n, n) nanotubes are the only truly metallic nanotubes.
- Other nanotubes satisfying $n - m \bmod 3 = 0$ but $n \neq m$ develop a small band gap (typically on the order of some tens of meV) and the degeneracy between higher energy subbands is lifted.
- Semiconducting nanotubes develop a chirality dependent band gap (with a term proportional to $\cos(3\theta)$).

4.2.3 Phonon Dispersion

Atomic vibrational motions of carbon nanotubes are very similar to those of graphene but due to their cylindrical symmetry they are separated into radial *breathing* modes (along the radial axis), transverse modes (along the azimuth angle axis), and longitudinal modes (along the length axis) [4.37]. The phonon band structure has been calculated by various methods including zone folding [4.38, 39], constant force [4.40, 41], tight-binding [4.42, 43] and ab initio methods [4.44–46]. Similar to the electronic structure, the phonon dispersion in SWCNTs is quantized and exhibits singularities specific to their 1-D nature.

Due to its honeycomb lattice containing two atoms in each unit cell, graphene phonon dispersion contains six modes, with two types of transverse and one type of longitudinal motions; hence three acoustic and three optical modes. There are two main consequences when wrapping a graphene sheet into an SWCNT. First, it introduces a periodic boundary condition along the circumference, which quantizes the corresponding wavevector. As a result, the 2-D graphene phonon modes are further split into a large number of subbands. If the SWCNT contains $2N$ atoms per unit cell, there are $6N$ phonon modes in total, many of which are degenerated (Fig. 4.5b,c [4.45]). The second consequence is that the curvature makes its three fundamental atomic motions different from those of graphene. Hence, the SWCNT phonon modes can be viewed as a mixture of 2-D graphene phonon modes [4.37]. The effect of such symmetry difference is significant for lower frequency modes. For instance, there are four acoustic modes in-

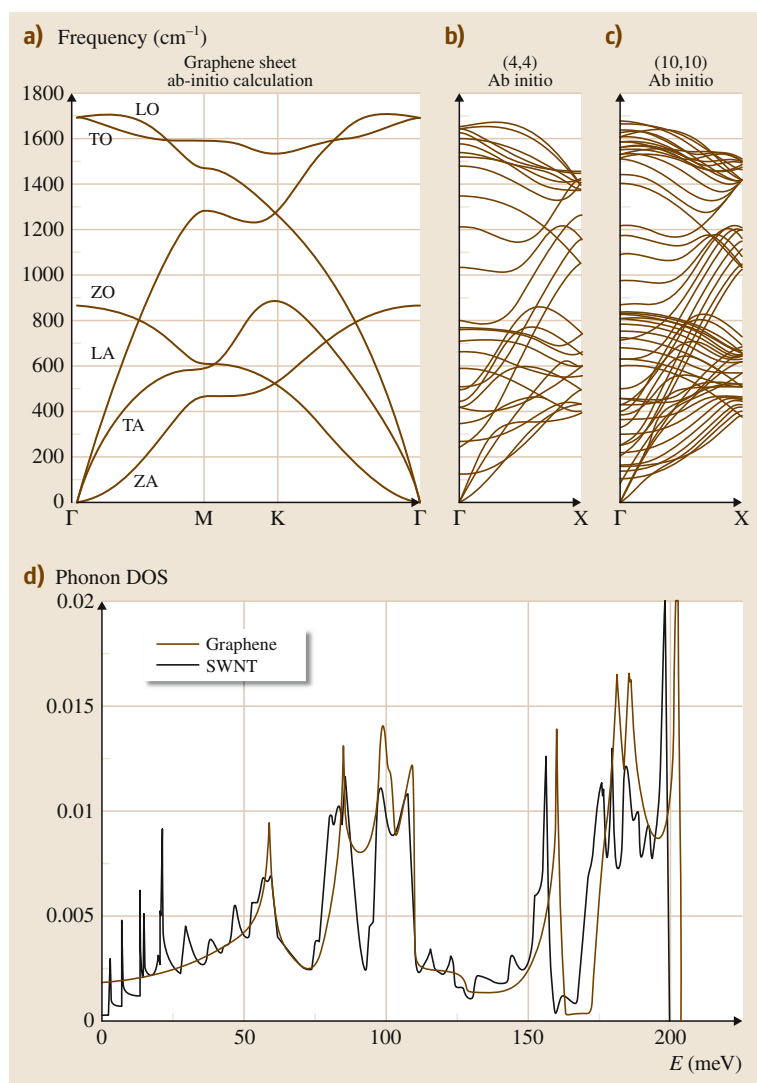

Fig. 4.5 (a). Ab initio dispersion relations for the (4,4) (b), and the (10,10) (c) nanotubes. In (c) and (d), thicker lines are used to mark two special branches: the acoustic band is a twist mode (torsional shape vibrations), the other (with finite frequency γ) is the breathing mode. (d) Phonon density of states of an isolated (10,10) SWCNT (solid line), compared to a 2-D graphene sheet. ((a–c) after [4.45], (d) after [4.48])

stead of three (Fig. 4.5b,c [4.47]; also see Fig. 4.25a for a larger view):

- A *longitudinal acoustic* (LA) mode, corresponding to motion of the atoms along the tube axis (similar to the LA mode in graphene).
- Two degenerate *transverse acoustic* (TA) modes, corresponding to atomic displacements perpendicular to the nanotube axis (a combination of in-plane and out-of plane TA modes in graphene).
- A *twist mode*, corresponding to a torsion of the tube around its axis (similar to the in-plane TA modes in graphene).

The *radial breathing mode* (RBM) is another important low-frequency mode, corresponding to radial expansion-contraction of the nanotube. It is similar to the out-of plane TA mode in graphene with zero energy at the center of the Brillouin zone, but becomes a mode with a finite energy due to the curvature. To first order, the energy of the RBM mode is inversely proportional to the diameter of the tube and presents chiral angle dependencies similar to electronic subbands [4.44].

Figure 4.5d shows the calculated phonon density of states of a (10, 10) tube and a graphene sheet side by side [4.49]. One of the main features is that the

SWCNT phonon density of states has a number of sharp peaks (van Hove singularities) due to its 1-D structure. Such a difference is more profound at lower frequencies, because low frequency phonon modes are more reflective of the symmetry of carbon nanotubes, while higher frequency modes are more reflective of carbon-carbon bonding. For this nanotube the calculated energy of RBM mode is 21.7 meV while the first van Hove singularity appears at about 2.5 meV. Van Hove singularities have been observed by neutron scattering experiments [4.48], thus confirming theoretical calculation.

When carbon nanotubes are bundled together, the intertube interaction will introduce dispersion along the transverse (intertube) direction. This will reduce the density of phonon states at low frequency, which has profound effect on the thermal properties of SWCNTs [4.49]. However, the heterogeneous nature of carbon nanotube bundles make theoretical calculation difficult. Figure 4.6 shows a tight-binding calculation for the case of graphite-like SWCNT bundles [4.50]. It can be seen that the intertube acoustic modes have fairly flat dispersion and the overall phonon frequencies are much less than those of intratube modes. Consequently, these modes should have very low Debye temperature

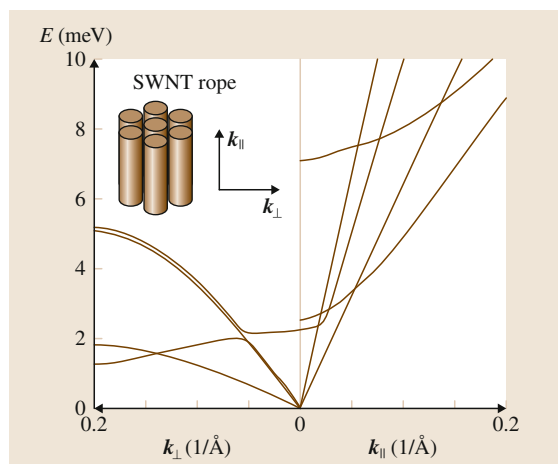

Fig. 4.6 Calculated low-energy phonon band structure of a SWNT bundle, for the case of graphite-like (strong) coupling

Θ_D and their contributions are only significant at very low temperature. The intratube modes are also different from those for SWCNT showing a shift in frequency, which mostly affects low frequency modes or small diameter SWCNTs [4.37, 51].

4.3 Synthesis

Over 20 years after the first batches of carbon nanotubes (CNTs) were synthesized and documented as such [4.1], CNTs continue on a steady trajectory toward industrial applications while many of the remaining challenges of growth continued to be ironed out. Whereas CNT growth has been a dynamic topical area for the past few decades, the gap between readily available products incorporating CNTs and the progression of studies in this area remains significant. In recent years, it has been estimated that the capacity for production of multi-walled CNTs could be as high as 300 to/yr, whereas that of single-walled CNTs could be as high as 7 to/yr [4.52]. However, the challenge required to further push production levels is to build a global market for CNT-based products that will instigate further scale-up production based on cost, safety, and material performance, and to develop understanding of CNT growth that will aid in the design of cheaper, more efficient synthesis techniques. One drawback to industry is that many of the largest potential CNT markets require specific homogeneous properties, even though most large-scale CNT synthesis techniques yield mixtures of CNTs with dif-

ferent diameters and physical properties. This motivates research efforts continuing in the area of CNT growth to understand how to tighten the CNT diameter and property distribution by building a strong understanding of the growth processes and mechanisms. However, there is still a market even for wide-distribution multi-walled CNTs that can be produced at low cost in bulk quantities for their use as structural enhancers in materials.

The purpose of this section is to introduce the reader to the different techniques utilized to synthesize carbon nanotubes in addition to the different types of carbon nanotubes that can be produced using these methods. The caveat to this section is that the sheer breadth of techniques utilized in CNT growth makes it challenging to present a unified picture of CNT growth processes explaining every observation made thus far. A myriad of unique processes and systems have been utilized to grow CNTs, often reporting conflicting mechanistic results. Therefore, this section will focus on the ideas that have been accepted and have the capability to apply broadly to the vast majority of growth techniques discussed.

4.3.1 Substrate-Free Growth Techniques

In general, one can separate the growth of CNTs into two different categories: substrate-free CNT growth and substrate-bound CNT growth. By far, substrate-free CNT growth processes make up the majority of the large-scale industrial efforts due to the ease of scaling such techniques to implement continuous processes as opposed to operating using batch processes. From a historical perspective, two primary techniques have built the foundation of substrate-free CNT growth processes, which are (i) arc discharge [4.55, 56] and (ii) laser ablation [4.57]. In an arc discharge growth process, illustrated in Fig. 4.7a, two graphite electrodes are utilized in a chamber with an inert gas. A DC power supply is connected across the two electrodes (or rods) that passes electric current through the electrode configuration. This creates a discharge that consumes one of the electrodes and leaves a deposit on the other electrode that contains carbon nanomaterials that can vary in composition depending on the specific conditions utilized. One can tune the process to produce primarily multi-walled CNTs using two standard graphite electrodes to a process that produces single-walled CNTs using metal catalysts such as Ni, Fe, Mo, or Co doped into the electrode. Arc discharge is the most straightforward approach to synthesize carbon nanotubes, but its application as a large-scale production technique suffers due to the moderate yield of CNTs (often between 30–50%) amidst a variety of other carbons that requires one to employ post-process separation techniques to achieve well-defined samples. However, arc discharge processes predate carbon nanotubes and were readily employed in the synthesis of carbon whiskers and C₆₀ decades before the report by Iijima in 1991 [4.58]. It is suggested that processes to form carbon materials using arc discharge date back to the 1960s, and closer analysis of

the soot in these materials would have revealed carbon nanotubes.

Laser ablation growth of CNTs (Fig. 4.7b), on the other hand, is a process whereby the energy is supplied to the graphite target using either a continuous wave or pulsed laser, in comparison to a DC power supply in arc discharge. In laser ablation growth, the laser hits a hot target, which typically involves graphite with a catalytic metal (Ni, Fe, Co, etc.) doped into it, and vaporizes the target. Downstream of the target, a water-cooled condenser collects the product of the vaporized carbon/metal mixture that is carried using a flow of inert gas, such as Ar. Laser ablation processes can also be tuned to yield either single-walled CNTs or multi-walled CNTs based on the variation of parameters in the growth process such as the laser wavelength, laser power, laser pulse duration, furnace temperature, and graphite target composition. In particular, a low metal : graphite ratio in the target and a high furnace temperature (typically $\approx 1200^\circ\text{C}$) is generally associated with good quality crystalline single-walled CNTs, whereas greater amounts of metal yields multi-walled CNTs, and lower furnace temperatures compromise crystallinity of the CNT tube walls. Today, laser ablation and arc discharge processes are still employed readily in the research lab, although industry scale-up efforts have typically not incorporated these techniques due to the *batch-by-batch* nature of these processes and the common difficulty of getting mixtures of CNTs and amorphous carbons, metals, or fullerenes. However, significant progress has been made in utilizing processes such as laser ablation to yield controllable double-walled CNTs with moderately small diameters (2–3 nm) compared to other techniques.

Aside from these techniques, there are a myriad of other processes that have been developed and adopted for substrate-free CNT synthesis. Many of these techniques represent a form of chemical vapor deposition

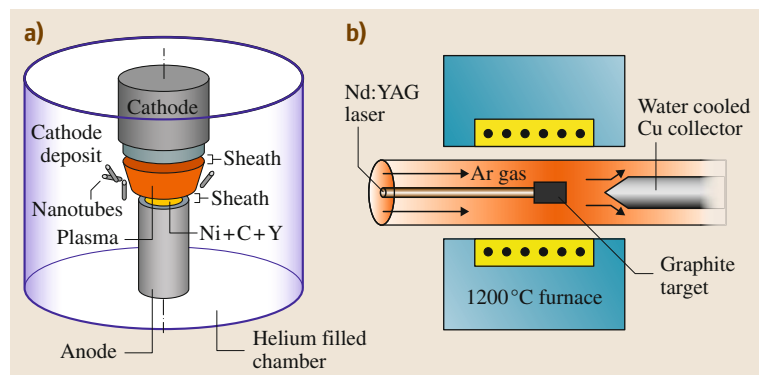

Fig. 4.7a,b Illustration of (a) an arc-discharge apparatus and (b) a laser ablation apparatus for growing carbon nanotubes. ((a) After [4.53]. (b) After [4.54])

(CVD) that can be scalable to large areas or can produce bulk quantities using cost-effective continuous processing. Generally, CVD techniques for CNT growth involve the reaction of a feedstock gas that contains carbon with nanoscale metal catalyst particles inside a heated reaction zone. For substrate-free synthesis processes, the metal is typically supplied during the process. Two notable processes that have proved capable of industrial-scale production are the HiPco process and fluidized bed CVD. The HiPco process was first designed at Rice University, with reports as early as 2001 documenting lab-scale SWNT production at 0.45 g/day [4.59]. The HiPco process is a form of CVD where an organometallic compound, such as $\text{Fe}(\text{CO})_5$, is fed into a reaction zone at high pressures (up to 50 atm) and high temperatures (900–1100 °C). This process causes the organometallic compound to decompose into small, nanoscale metal clusters that catalyze the CO disproportionation reaction to form by-products of CO_2 and single-walled CNTs. Although additional processes for synthesizing single-walled CNTs have been developed on an industrial front in recent years, much of the widespread CNT research efforts over the past decade can be attributed to the HiPco process.

In addition to HiPco, another key CVD-based process that has demonstrated significant potential for large-scale production is the fluidized bed CVD (FB-CVD) process [4.62]. In this process, illustrated in Fig. 4.8, feedstock gases and catalyst material are fed into the reaction zone forming CNTs that are then collected in a continuous fashion. In some cases, the FB-CVD process involves two distinct reaction zones whereby a catalyst precursor reacts in the first zone forming the catalytic material, and this then flows downstream to the reaction zone where the CNTs form through reaction with this catalytic material. The benefit of this process is that the catalyst source is continuous, enabling the development of highly scalable CNTs with controllable properties in many cases. However, the drawback to FB-CVD is often the excess metal present in the CNTs that can be difficult to remove, and the difficulty achieving the level of precision in growth processes that can be comparable to fixed substrate-based CNT growth techniques.

4.3.2 Substrate-Bound Growth Technique

Whereas substrate-free growth techniques have been the medium for bridging the CNT synthesis effort to the industrial marketplace, substrate-bound CNT growth represents a growth form that is more tailored to

Fig. 4.8 Schematic diagram of a fluidized bed chemical vapor deposition system. (After [4.60])

Fig. 4.9 (a,b) TEM images of catalyst particles that grow CNTs supported on Ta and SiO_2 . (c) Schematic showing how the substrate supporting the particles dictate whether tip growth (SiO_2) or base growth (Ta) is achieved. (After [4.61])

electronics or specialized fields. Substrate-based CNT growth is almost always based on variations of the CVD growth technique and involves a substrate that usually supports both the CNTs formed during growth in addition to the catalyst material that grows the CNTs. In substrate-bound CVD growth, there are two types of growth modes that are well-accepted, which are (i) *base-growth* where growth of CNTs occurs while the layer of catalyst nanoparticles remains at the interface with the growth substrate, and (ii) *tip-growth*, where the catalyst nanoparticles lift off the substrate and are supported by the growing CNT during the growth process (Fig. 4.9). In a typical substrate-bound CNT growth ex-

Fig. 4.10 Schematic of thermal CVD system setup generally utilized in aligned CNT growth (courtesy Atomic Physics, Göteborg University)

periment using thermal CVD, the substrate containing the catalyst is placed into a heated zone, and a flow of carbon feedstock initiates the nucleation and growth of the CNTs. Variations of this process include plasma-enhanced CVD [4.63] and hot-filament CVD [4.64], where the plasma or hot filament act as energy sources to form reactive species for catalytic growth that would otherwise not form in a thermal CVD environment. A general illustration of a thermal CVD system utilized in these sort of experiments is shown in Fig. 4.10.

One of the most remarkable observations for the substrate-based growth of CNTs was the notion that a thin, uniform layer of catalytic material can be deposited onto the surface of a substrate, and the growth from this catalytic layer can result in self-oriented, aligned arrays of CNTs. Whereas this was initially shown for multi-walled CNTs in 1999 [4.66], by 2004 a few groups had demonstrated this for single-walled CNTs as well [4.67, 68]. One of the most notable observations early-on was that the addition of a small amount of H₂O during the catalytic reaction in addition to the carbon feedstock can accelerate the growth process dramatically, yielding millimeter-scale single-walled CNT arrays that grow in 10 min or less. Since the CNTs produced in this novel synthetic approach – which themselves are only a few nanometers in diameter – can be greater than a centimeter [4.69] in length and grown in structures where alignment is inherent from the stage of growth, these materials drew excitement from researchers. Figure 4.11 shows an SEM image of a short CNT forest where the individual CNT bundles are visible. In particular, substrate-free growth techniques such as arc discharge, laser ablation, or HiPco yield tangled CNTs that have submicron lengths. The challenge that remains for these materials is that

Fig. 4.11 SEM image of a vertically aligned carbon nanotube array (after [4.65])

substrate-based aligned CNTs are produced in a batch process using high temperatures that is not amenable to scalable production. Additionally, the limitations of many growth processes to specific substrates, such as alumina, have created roadblocks to the diverse applications envisioned for these materials. Recent efforts have made progress in growth of CNTs on conductive Cu substrates and at low temperatures [4.70], but a better understanding of the mechanisms behind CNT growth needs to be elucidated prior to large-scale advances in these areas. Fortunately, aligned CNT arrays have emerged as excellent test-beds to analyze the mechanistic aspects of CNT growth. Unlike most substrate-free CNT growth processes, aligned CNTs nucleate at virtually the same time and are uninhibited in many cases by significant steric hindrances that can alter the catalytic properties of randomly aligned materials. Therefore, one can use aligned CNT growth to probe quantitative and bulk-scale characteristics of the CNT growth and termination mechanisms that are relevant to all CNT growth processes.

4.3.3 Growth Mechanisms

The identification of specific mechanisms related to CNT growth remains controversial due to the wide variety of observations in growth processes that a single, unified mechanism would have to explain. However, it has been most readily accepted that CNT growth occurs via a vapor–solid–solid (VSS) model or a vapor–liquid–solid (VLS) model that has been readily employed for catalyst-based synthetic processes of other nanomaterials. In some cases for high temperature (> 900 °C) CNT growth, it is expected that the catalyst particles are in liquid phase whereas in lower temperature processes (< 700 °C) it is expected that catalyst particles

exist as a solid. It should be noted that the fast growth rates observed in CNT array growth can be modeled using diffusion parameters relevant to solids [4.71]. In these simple models, the hydrocarbon feedstock reacts with the catalyst particle and provides carbon that diffuses to the catalyst particle. In the initial phases of growth, a carbon cap precipitates on the surface of the particle and lifts off to result in CNT nucleation. Following nucleation, a constant carbon flux to the particle leads to the diffusion of carbon through the particle and to the edges of the growing CNT. In the simplest theoretical case, this becomes a steady-state system where a constant flux of carbon is supplied to the particle and the nanotube grows at a constant rate. However, from an experimental perspective, carbon nanotube synthetic processes terminate at some point, which is still not completely understood. This is believed to be a function of a process of *carbon overcoating* where amorphous carbon builds up on the catalyst particle and, over time, renders it inactive in growing CNTs. TEM studies have identified that morphology changes of the catalyst in the form of Ostwald ripening or other kinetic processes that occur due to the high free energy of catalyst nanoparticles and their exposure to the high temperature growth conditions may play a key role in termination processes as well, especially when the catalyst is supported by a solid surface [4.72].

Theoretical models of this process, one which is illustrated in Fig. 4.12, have been able to unify the interplay between multi-walled and single-walled CNT growth through the simple concept of carbon flux that

Fig. 4.12 Schematic showing the complex processes occurring during the catalytic growth of CNTs based on a model from Puretzky et al. (After [4.73])

is incident on the particle [4.71]. In a carbon starved environment (where the carbon flux is smaller than the diffusion rate), the result will be the nucleation of CNTs with only one wall whose outer diameter matches the particle size. Greater flux of carbon will result in the formation of multiple walls in the CNT. Whereas these ideas may oversimplify the challenges in understanding CNT synthetic processes, it is hoped that some unified model will emerge in the future that can establish a connection between the variable processes and systems used in CNT growth and the mechanisms that are at play in dictating nucleation, growth, and termination of CNTs.

4.4 Optical Properties

Because of their diameter-dependent direct band gaps, SWCNTs are promising for next-generation optoelectronic components. At the same time, their one-dimensionality is ideal for the study of 1-D excitons, whose properties remain largely unexplored despite predictions that they should behave very differently from excitons in higher dimensions [4.74, 75]. However, intrinsic optical properties of individual SWCNTs were difficult to probe for many years because of the effects of bundling and resulting tube-tube interactions in typical ensemble samples. During the past decade, much progress has been made in optical studies of SWCNTs, stimulated in part by the 2002 discovery of band gap photoluminescence (PL)

from individually suspended SWCNTs in aqueous solution [4.76]. These samples have created opportunities to perform spectroscopy of individual nanotubes of specific chiralities, allowing exploration of their intrinsic optical properties. PL excitation (PLE) spectroscopy [4.77–88], Raman spectroscopy [4.89–110], ultrafast optical spectroscopy [4.111–140], micro- and nano-spectroscopy [4.141–163], and magneto-optical spectroscopy [4.11, 15, 17, 156, 157, 164–170] of individualized SWCNTs are currently under investigation, revealing fundamental properties of 1-D excitons and phonons.

Due to the strong 1-D quantum confinement, photo-created electron-hole pairs form excitons, i. e., hydro-

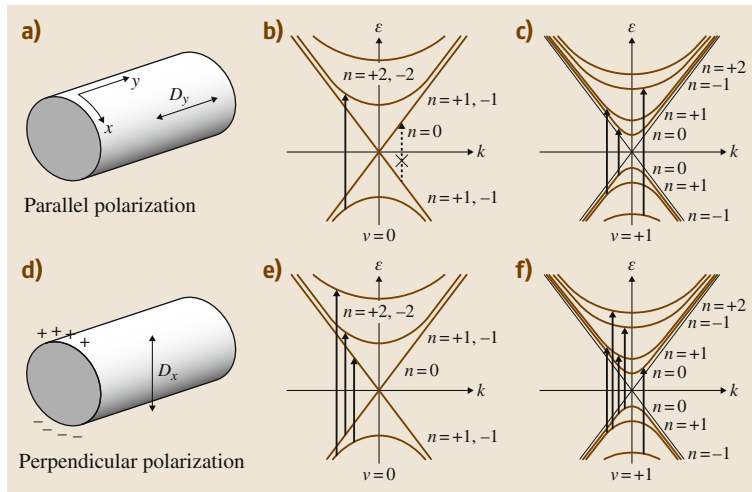

Fig. 4.13 (a–c) Incident light polarized parallel to SWCNT axis for a metallic SWCNT and a semiconducting SWCNT with allowed transitions indicated ($\Delta n = 0$). (d–f) Incident light polarized perpendicular to SWCNT axis for a metallic and semiconducting SWCNT with allowed transitions indicated ($\Delta n = \pm 1$). (After [4.23])

genic, Coulomb-bound electron–hole pairs [4.171]. In fact, in an ideal 1-D system, the binding energy of excitons has long been known to be infinite [4.172, 173]. Later, the binding energies of excitons in SWCNTs were experimentally determined to be hundreds of meV [4.174, 175], a significant fraction of their bare band gap, making SWCNTs one of the first systems in which to investigate excitons in the 1-D quantum limit.

4.4.1 Optical Absorption and Photoluminescence

Interband optical properties of SWCNTs arise from their structure-dependent attributes such as diameter and chiral angle as well as their electronic type (i. e., metallic or semiconducting). Therefore, optical spectroscopy provides a powerful tool for determining these attributes and their distributions in a given macroscopic sample.

First we will summarize the selection rules for interband absorption and emission in SWCNTs. If the photon momenta are small compared to the crystal momentum of the Bloch electrons, then approximate conservation of total linear momentum disallows *horizontal transitions*. Hence only *vertical transitions* are observed.

As in any solid, only vertical transitions are possible due to conservation of total linear momentum. This is because the photon momenta are small compared to the crystal momentum of the Bloch electrons. In the case of 1-D systems like SWCNTs, only transitions between states with nearly equal linear momenta along the tube axis are allowed. Since valence and conduction subbands in SWCNTs can be indexed by

their angular momentum along the tube axis [4.23] (Fig. 4.13), angular momentum conservation must be considered for optical absorption and emission. Light polarized parallel to the tube axis does not have any angular momentum, and thus only transitions between states having equal angular momentum (i. e., the same subband index) are allowed for this polarization. In contrast, light polarized perpendicular to the tube axis can impart angular momentum to the circumference of the tube. This is visualized by thinking of the equal mixture of right- and left-handed circularly polarized light that comprises this polarization configuration; left-handed (σ_-) light changes angular momentum by -1 and right-handed (σ_+) by $+1$. The perpendicular polarization, therefore, allows for transitions between states with a change in angular momentum of ± 1 . However, there is a strong depolarization effect for a perpendicular optical field [4.10, 176, 177], which suppresses absorption, making these optical transitions difficult to observe.

Experimentally, absorption spectroscopy is the simplest way to understand the basic characteristics of interband optical transitions in SWCNTs [4.76, 178–180]. Optical transitions occur between the valence and conduction bands, following the selection rules described before. The transitions are illustrated in Fig. 4.14. Because the transitions between states in the valence band vary in a precise way with the tube diameter in the optical regime, nanotubes were quickly identified as excellent candidates for optoelectronic applications. The interband transitions in SWCNTs reflect the underlying crystal symmetry of the nanotube. Since most synthesized SWCNTs have diameters ranging

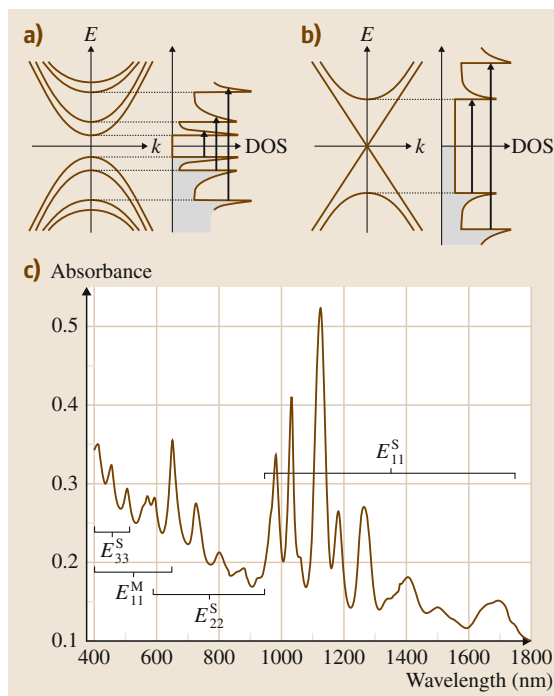

Fig. 4.14 Energy band diagram and density of states for (a) the E_{11} , E_{22} , and E_{33} transitions for semiconducting nanotubes, and (b) the E_{11} and E_{22} transitions for metallic nanotubes. The occupied states are expressed by the gray color. (c) Optical absorption spectrum of HiPco SWCNTs in a wide energy range from UV to IR. (Note that the first (second) of the subscripts of E_{ii} refers to the conduction (valence) subband index.) (After [4.8])

from 0.5 to 1.5 nm, the E_{11} and E_{22} transitions range from 800 meV to 3 eV. With increasing purity and individualization, higher-order transitions (up to E_{66}) have been observed, as well as phonon side-bands.

Figure 4.14c shows an optical absorption spectrum for HiPco SWCNTs, displaying four absorption bands:

1. E_{11} transition in semiconducting tubes
2. E_{22} transition in semiconducting tubes
3. E_{11} transition in metallic tubes
4. E_{33} transition in metallic tubes.

Within each band, there are multiple absorption peaks, coming from different (n, m) species present in the sample. It is therefore difficult to determine the (n, m) distribution quantitatively, unless the sample is highly enriched in a single (n, m) species. However, the intensity ratio between absorption peaks of metallic tubes and absorption peaks of semiconducting tubes

Fig. 4.15 Typical PLE map for HiPco nanotubes suspended in aqueous SDS. (After [4.8])

allows a qualitative estimate of the population ratio between these two types.

In the process of photoluminescence (PL), a high energy photon is absorbed by the medium and then a lower-energy photon is emitted. The excited state in a SWCNT can, in principle, be any high energy state or anywhere in the continuum, but due to enhanced absorption, a resonance appears when the E_{22} transition is excited and emission comes from E_{11} transitions. This effect was first observed in SWCNTs by O'Connell et al., and it quickly became one of the most common characterization tools for nanotube materials. In a typical PL experiment, the sample is excited by a range of visible wavelengths, and the luminescence is measured over a range of near-infrared wavelengths. Plotting the measured light intensity against the emission and excitation wavelengths creates a *photoluminescence excitation* (PLE) map (Fig. 4.15). Contrary to absorption spectroscopy, this technique is not useful for probing metallic (and small band gap) nanotubes but has the advantage of being sensitive enough to assign chiralities of semiconducting nanotubes, as illustrated in Fig. 4.15. It has proven to be ideal for measuring large quantities of materials, especially when combined with other spectroscopic tools (e.g., resonant Raman and absorption), and provides statistical information which cannot be obtained with electron microscopy. In addition, PL experiments have been used to obtain an understanding of excitonic states associated with the 1-D nature and the fourfold degeneracy of the electronic band structure of these semiconductors.

4.4.2 Raman Spectroscopy

As a consequence of their unique 1-D band structure, resonant Raman scattering spectroscopy serves as a powerful technique for the characterization and study of carbon nanotubes. A variant of normal Raman scattering, resonant Raman scattering (RRS) measures the intensity and energy of incident photons that are inelastically scattered off matter. The change in energy of the scattered photon relative to the energy of the incident photon corresponds to a quantum of the material under investigation, in this case a vibrational or phonon mode of an SWCNT. The resonant aspect of the technique comes from the use of excitation laser energies that coincide with real optical transitions of the SWCNT, resulting in a resonant enhancement effect that increases the Raman scattering probability from about 1 in 10^7 to approximately 1 in 10^3 . The unique combination of the resonant nature of this technique with the highly anisotropic structure of carbon nanotubes allows for unconventional uses of vibrational Raman scattering to provide information on bulk and individual mechanical, electronic, and solution properties of these materials. One specific advantage of RRS over other optical methods is its ability to examine both semiconducting and metallic types of SWCNTs, regardless of aggregation state, doping, or number of defects.

The most widely used and intense Raman-active vibrational modes used for studying and characterizing

carbon nanotubes are shown in Fig. 4.16. The lowest frequency mode ($\approx 100\text{--}400\text{ cm}^{-1}$) appears only in carbon nanotubes and fullerene structures and is known as the radial breathing mode (RBM) [4.181, 182] (Sect. 4.2.3). It is an isotropic stretching vibration occurring in the radial direction perpendicular to the tube axis. Since its frequency varies inversely with nanotube diameter [4.181], it serves as one of the most common methods for optically determining the tube diameter of a particular SWCNT species.

When such data is taken using a tunable laser source, the excitation energy dependence of specific RBMs can be determined. The energy at which the RBM Raman intensity reaches a maximum corresponds to the incident and scattered photon resonances with the SWCNT optical transition. As a result both diameter and optical transition energy can be determined from RBM Raman measurements allowing for assignment of RBM Raman features to specific (n, m) SWCNT structures [4.90–93, 97]. Once the optical transition energies are known for individualized SWCNTs, RBM intensity excitation profile data can be used to determine aggregation state [4.183] and even relative (n, m) abundance [4.109, 184–186].

The G-band vibration, centered at $1550\text{--}1600\text{ cm}^{-1}$, is another very intense vibration and is common to all sp^2 -hybridized carbon [1,2]. It is an in-plane, C–C stretching mode which is isotropic in graphene but anisotropic in carbon nanotubes due to the curvature-induced inequality of the two bond-displacement directions which causes the phonon to split into two, the G^+ and G^- peaks. Because of the splitting of the G-band into two separate but related modes, the overall line shape and intensity of the G-band can identify whether the tubes undergoing resonance with the excitation laser are metallic or semiconducting, as shown in Fig. 4.16 [4.103, 181, 187–190]. Furthermore, shifts in the G-band frequency can be observed due to doping via charge transfer resulting in the so-called *Eklund shift* [4.191]. With the application of uniaxial mechanical strain, the effective spring constants in each bond displacement direction can be further modified causing shifts in both G^+ and G^- frequencies as well as shifts in the observed optical transition energies, making the G-band a sensitive monitor of mechanical strain [4.192].

Another important mode is the D-band phonon, an out-of-plane bending mode with frequency 1300 cm^{-1} [4.181, 182]. This mode is normally Raman-inactive in pristine or perfect sp^2 -carbon due to symmetry considerations, however, when the translational symmetry of the extended structure of graphene, graphite, or a car-

Fig. 4.16 A typical resonant Raman spectrum of a bulk SWCNT sample, taken at 785 nm excitation, for SWCNTs produced at Rice University. The spectrum illustrates the primary vibrational modes observed for SWCNTs, namely the RBM, D-band, G-band and G'-band

bon nanotube is broken by some sort of disorder, the D-band becomes Raman active and its intensity generally increases with the degree of disorder. This is why the D-band is often referred to as the *disorder* or *defect* peak in graphitic-like materials. This disorder can be actual bond dislocation defects, chemical functional groups, physisorbed molecular species, charge transfer complexes, etc., i. e., anything that can cause a localization of electron density in the otherwise delocalized π -bonding network.

Lastly, the G' -band ($2600\text{--}2700\text{ cm}^{-1}$), also common to all sp^2 -hybridized carbon, is a dispersive, second-order Raman mode highly sensitive to small changes in electronic and vibrational structure [4.182]. Specifically, the excitation dependence of the G' -band can be used to measure the dispersion of the optical transition under resonance, an important characteristic for understanding electronic band structure. Such *mapping* of the G' -band excitation profile allowed the first experimental confirmation of the trigonal warping effect in the electronic density-of-states [4.194].

Raman scattering provides information only about the crystal structure of carbon nanotubes. However, when combined with the resonance effect, the intensity of the scattered photons can provide quantitative information about the electronic, aggregation, chemical, and mechanical states of carbon nanotubes. Such information is invaluable to future research tasked with turning these molecules into macroscopic materials with tailor-made properties.

4.4.3 Resonant Rayleigh Spectroscopy

Resonant Rayleigh scattering or resonant elastic light scattering has recently become a popular tool for the optical study and rapid characterization of nanotube samples [4.195–197]. This technique can rapidly identify excited states in both metallic and semiconducting SWCNTs due to its high scattering intensity when combined with a broadband, tunable excitation source. *Sfeir* et al. [4.195] made initial observations of scattering peaks in the excitation spectra consistent with expected optical transitions for both semiconducting and metallic species. In particular, the excitation spectra of metallic SWCNTs exhibited peak splitting which were attributed to trigonal warping of the graphene Brillouin zone. In subsequent studies by *Sfeir* et al. [4.196] and *Berciaud* et al. [4.193], individual nanotubes were structurally identified using electron beam diffraction via transmission electron microscopy prior to Rayleigh scattering measurements, allowing a direct assignment of optical

Fig. 4.17a,b Rayleigh scattering excitation spectra of (a) specific semiconducting and (b) metallic single-walled carbon nanotube chiralities. Vertical dashed lines indicate the energy position at which phonon sidebands are expected. Insets (b) are magnifications of the energy regions where phonon sidebands are expected, revealing no apparent feature. (After [4.193])

spectra obtained via resonant Rayleigh scattering to individual (n, m) species, as shown in Fig. 4.17. Semiconducting features were assigned to E_{33}^S and E_{44}^S excitonic optical transitions, while those of metallic SWCNTs were attributed to those of E_{11}^M . In addition, spectra of semiconducting SWCNTs show smaller, higher-energy features, located $\approx 200\text{ meV}$ above the main excitonic optical transition peak, attributed to phonon sidebands.

More recently, *Liu* et al. [4.197] combined electron beam diffraction with in situ Rayleigh scattering to measure 206 optical transitions of (n, m) -identified nanotubes. In particular, for nanotubes spanning diameters $1.4\text{--}4.7\text{ nm}$, optical transitions were measured for semiconducting species ranging from E_{33}^S up to E_{77}^S , and for metallic species ranging from E_{11}^M up to E_{33}^M . From this broad range of data collected via Rayleigh scattering spectroscopy along with existing E_{11}^S and E_{22}^S data collected via photoluminescence excitation spectroscopy, an empirical equation was produced to predict optical transition energies with appropriate (n, m) - and E_{ii} -dependent parameters, providing a predictive tool for assigning measured optical spectra to specific SWCNT chiralities over a broad range of experimentally relevant energies.

One particularly useful application of Rayleigh scattering spectroscopy is the wide-scale characterization of

many nanotubes simultaneously [4.198]. Using a wide-field laser illumination in a dark-field microscope geometry and refractive-index-matching, Joh et al. were able to Rayleigh image entire chips containing many different SWCNT species as a function of laser excitation energy. Combined with atomic force microscopy (AFM), this improvement in experimental setup allows not only the identification of nanotube growth but also the rapid determination of optical spectrum and diameter from Rayleigh scattering and AFM measurements, respectively, facilitating assignment to specific (n, m) structures [4.198].

4.4.4 Ultrafast Spectroscopy

Ultrafast spectroscopy allows the interrogation of carrier and phonon dynamics in condensed matter systems. As the rise and relaxation times of these ultrafast phenomena are on the order of 1 ps, they can be observed by using femtosecond laser pulses. One of the most popular tools for this is time-resolved pump-probe measurements. When a strong optical pump pulse from a femtosecond laser generates electron-hole pairs, the

concomitant changes in the properties of the material (e.g., Raman scattering, absorption, and reflectivity) are detected by a weaker probe pulse, and the delay is controlled by the experimenter.

Time-resolved pump-probe spectroscopy is a suitable method for measuring carrier dynamics, such as distribution functions and relaxation mechanisms. Using this method, one can explore carrier dephasing processes, carrier-carrier scattering, carrier-phonon scattering, and radiative and nonradiative recombination processes [4.111, 113, 115, 123, 199–202].

Figure 4.18 shows typical differential transmission ($\Delta T/T_0$) signals as a function of delay between pump and probe pulse. Two traces taken at 0.89 eV (1393 nm) and 1.60 eV (775 nm) correspond to E_{11} and E_{22} ranges, respectively. In both cases, a positive differential transmission is consistent with band filling, and the shorter decay time is explained by a nonradiative intraband relaxation process [4.203]. The slower decay time only found in the E_{11} range ($h\nu = 0.89$ eV in Fig. 4.18) can be explained as a radiative interband recombination, because the signal is resonantly enhanced when the photon energy is consistent with an interband absorption peak [4.111, 113, 200].

Coherent phonon (CP) spectroscopy is a powerful characterization tool, especially for SWCNTs. It allows direct measurement of excited state phonon dynamics in the time domain, including phase information and dephasing time. This information cannot be directly obtained via Raman spectroscopy. CP spectroscopy has several more advantages over Raman spectroscopy, including high resolution and narrow linewidths, no Rayleigh scattering, and no photoluminescence. Hence it allows characterization of metallic as well as semiconducting nanotubes, whereas PLE is incapable of characterizing metallic nanotubes.

Since the observation of coherent phonons in SWCNTs by Gambetta et al., many studies of the RBM and G-mode coherent phonons in SWCNTs have been published [4.129, 130, 134, 135, 137, 204, 205]. Figure 4.19a shows a coherent phonon oscillation signal in the time-domain [4.137]. To determine the frequencies of the excited lattice vibrations, one can perform a fast Fourier transformation (FFT) of the time-domain oscillations, such as is shown in Fig. 4.19b. The multiple peaks in the lower frequencies correspond to the RBM, which indicates that the SWCNT sample contains several chiralities that are resonantly excited at 840 nm (1.48 eV) [4.130]. Since the CP spectrum has high resolution, the peaks can be used to accurately determine the chiral index of the SWCNTs [4.206].

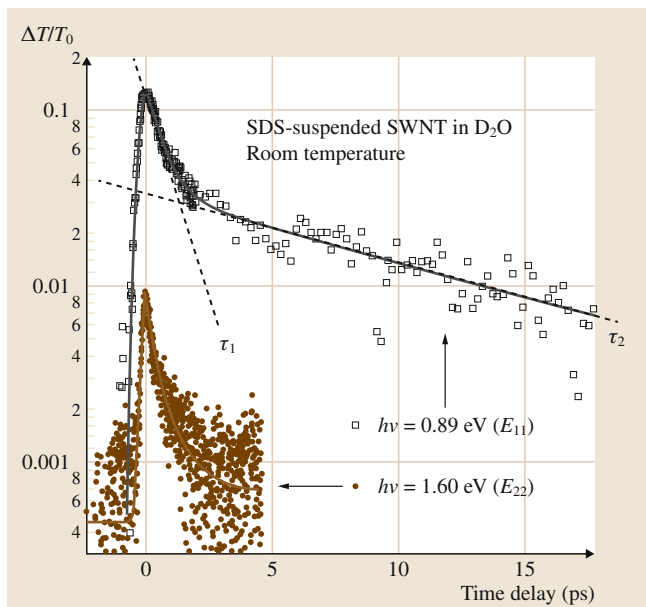

Fig. 4.18 Ultrafast pump-probe data at two wavelengths, corresponding to first and second subband transitions. A very fast single decay is seen in the second subband case while two decay components ($\tau_1 \approx 770$ fs and $\tau_2 \approx 10$ ps) are clearly seen in the first subband case. Solid lines show Gaussian and exponential fits in the appropriate delay regimes. (After [4.113])

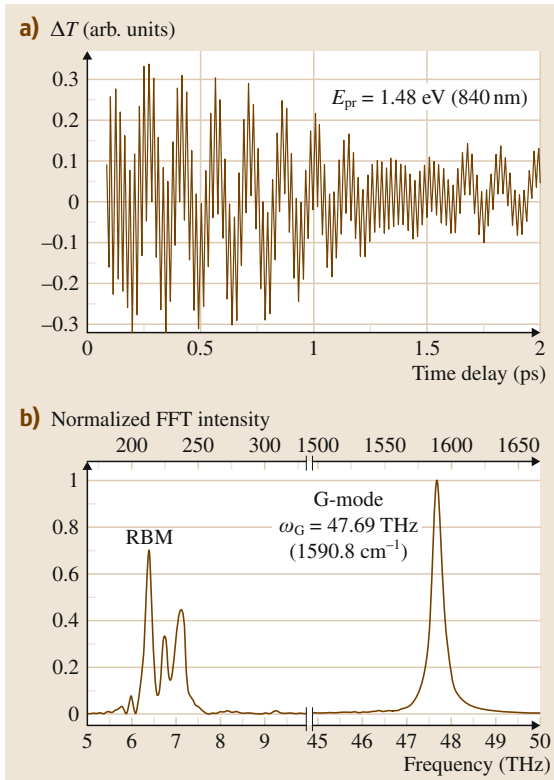

Fig. 4.19 (a) Transmitted intensity modulations due to coherent phonon oscillations in SWCNTs, which were extracted from the pump-probe signal for pump and probe energies of 1.55 eV (800 nm, E_{pu}) and 1.48 eV (840 nm, E_{pr}), respectively. The beating pattern arises from superposition of the CP oscillations from the RBM and G-mode. (b) Corresponding Fourier-transformed spectrum showing radial-breathing modes (RBMs) at 6.0–7.5 THz (200–250 cm^{-1}) and G-mode phonons at 47.69 THz (1590.8 cm^{-1}). (After [4.137])

The peak at 47.69 THz (1590.8 cm^{-1}) corresponds to G-mode phonons of SWCNTs. With regard to the G-mode, Kim et al. recently presented a clear picture for the dephasing of G-band phonons by random frequency modulation via interaction with the RBM through anharmonicity [4.136, 137].

Using a pulse-shaping technique [4.207], chiral-selective excitation has been achieved for studying the physical properties of single-chirality SWCNTs [4.134]. Figure 4.20a shows typical CP oscillations (Fig. 4.20a, left) and their Fourier transformed spectrum (Fig. 4.20a, right). By introducing multiple pulse trains with different repetition rates (7.07–6.15 THz), a coherent

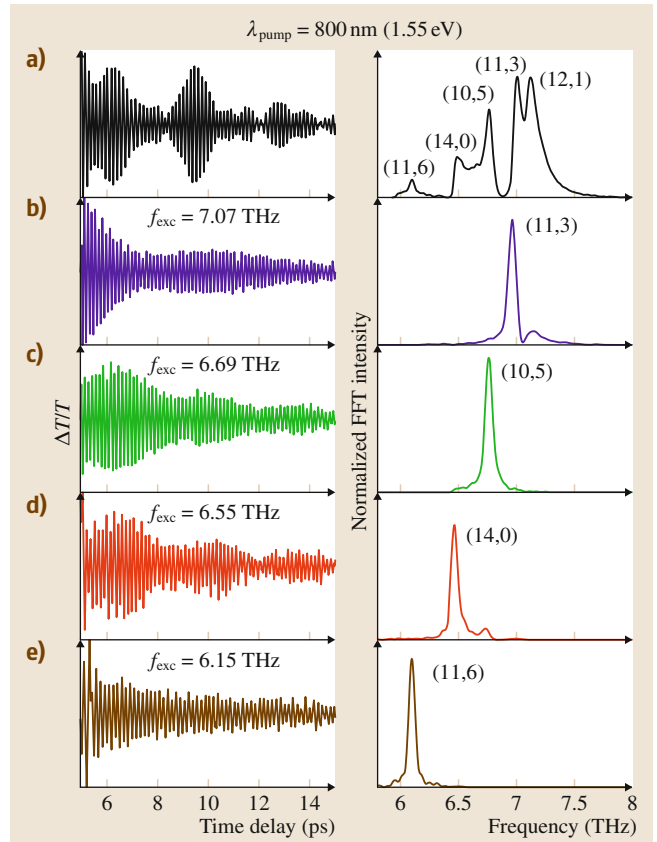

Fig. 4.20 (a) Left: time-domain transmission modulations of the probe due to coherent RBM vibrations in ensemble SWCNT solution generated using standard pump-probe techniques without pulse shaping. (a) Right: Fourier transformation of time-domain oscillations with chirality-assigned peaks. (b–e) Left: time-domain coherent RBM oscillations selectively excited by multiple pulse trains via pulse shaping with corresponding repetition rates of 6.15, 6.55, 6.69, and 7.07 THz. (b–e) Right: Fourier transformations of corresponding oscillations, with their dominant nanotube chirality (n, m) indicated. (After [4.134])

RBM oscillation is selectively excited, as shown in Fig. 4.20b–e, respectively. For instance, by choosing a pump repetition rate of 7.07 THz, the (11,3) nanotubes can be excited selectively, as shown in Fig. 4.20b. Note that the accuracy of selectivity depends on the number of pulses in the tailored pulse train.

4.4.5 Excitonic Effects

1-D Coulomb interaction differs significantly from systems with other dimensions. For example, the ex-

citon binding energy becomes infinite in an ideal 1-D electron-hole system [4.172, 173, 208]. In addition, the Sommerfeld factor, the ratio of the exciton continuum to the free electron-hole pair above the band edge, has been shown to be less than 1 in 1-D systems [4.74, 75]. 1-D excitons in SWCNTs [4.209] seem to be even more peculiar. Early experimental PLE results (e.g., [4.80]) indicated that interband excitation energies are *higher* than those expected from band structure calculations based on simple tight-binding models. This blue shift is totally against our conventional wisdom that excitonic binding should red shift the excitation energy from the band edge. Ando's pioneering theoretical work [4.210, 211] indicates that there is a significant blue shift from the single-particle band gap (which is what tight-binding calculations yield) due to quasi-particle corrections. This blue shift is expected to exceed the excitonic binding energy, and thus, the net effect is a blue shift. A number of more recent theoretical studies [4.177, 212–229] not only confirmed these predictions and provided estimates for the exciton binding energies but also raised an array of new issues, questions, and predictions, including the intrinsic radiative lifetimes, the existence of *dark* excitons, and the stability of excitons in metallic carbon nanotubes. Two-photon PLE studies [4.174, 175] have successfully determined the exciton binding energies to be very large (300–500 meV). Excitonic signatures have also been detected in absorption spectra of metallic nanotubes [4.180]. Furthermore, recent temperature-dependent magneto-optical studies have provided new insight into the excitonic fine structure in SWCNTs [4.165–169], including the direct measurement of dark-bright splitting values in individual SWCNTs [4.156, 157].

The existence of two equivalent valleys in momentum space, K and K' valleys, combined with strong short-range Coulomb interactions (intervalley mixing and exchange), produces an intriguing excitonic fine structure in SWCNTs [4.223, 231]. There are four combinations of lowest-energy excitons: two are direct excitons formed by linear combinations of KK and $K'K'$ electron-hole pairs and two are indirect excitons that are created by indirect $K'K$ and KK' electron-hole pairs. The latter are finite momentum exciton states that require a phonon-assisted transition to be optically created. Direct excitons are zero momentum states, which facilitates optical absorption and emission. However, the mixing of the KK and $K'K'$ transitions produces two wavefunctions that have opposite parity under transformations about the axis perpendicular to the tube

(sometimes referred to as the U symmetry axis). The lower (s -like, often called the $1g$ state) exciton state has even symmetry, while the upper state (p -like, $1u$ state) has odd symmetry. Since a photon will only couple with a state with odd parity (system overall has even parity), the upper state is optically active (*bright*) and the lower state is inactive (*dark*), which is a unique scenario whereby the lowest state is not the emissive one [4.214, 217, 219, 221–223, 231]. The $n = 2$ orbitals of the E_{11} exciton reverse the ordering of even and odd symmetry, such that the $2u$ (odd symmetry) has a lower energy than the $2g$ (even) state.

Experimentalists have exploited these symmetry-based transition rules to investigate SWCNT excitons. Since only the $1u$ exciton state couples to the light field by way of one photon, and $2g$ couples only using two photons, one can excite one-photon dark states and monitor the $1u$ luminescence (Fig. 4.21) [4.174, 175]. Using the difference between the excitation energy for E_{11}^{2g} and the emission energy of E_{11}^{1u} and assuming

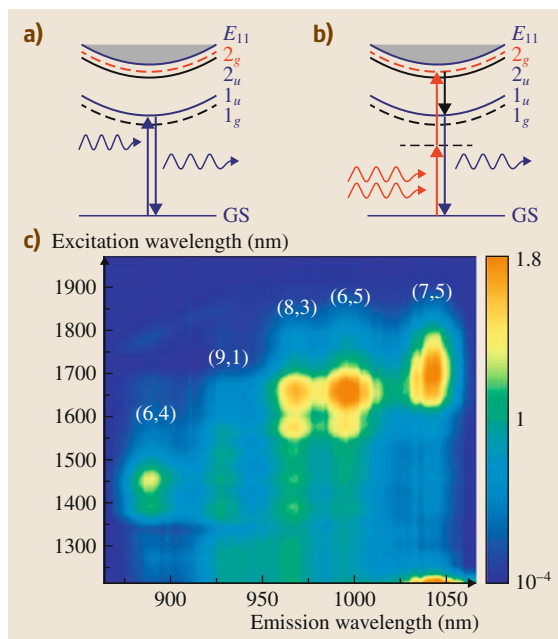

Fig. 4.21 (a) One photon can couple to the $1u$ state both as an excitation and emission. (b) Two photons can access even parity states, like $1g$ or $2g$. In two-photon spectroscopy, two photons excite a dark state while the bright, luminescent $1u$ state is monitored. (c) Experimental contour map of the PL intensity as a function of two-photon excitation (y-axis) versus one-photon emission (x-axis). (After [4.230])

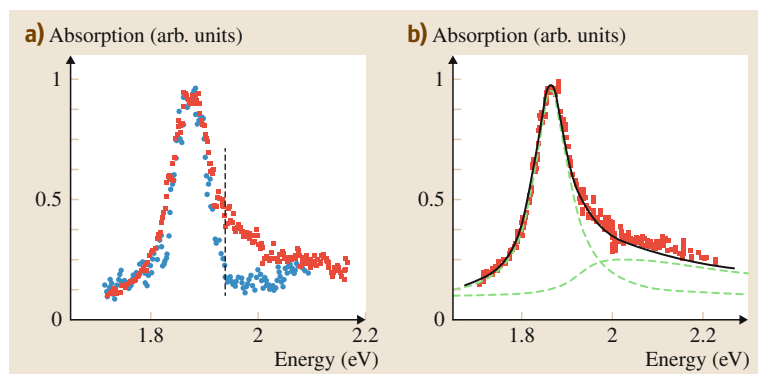

Fig. 4.22 (a) Absorption spectrum of a (21,21) metallic nanotube (red symbols) and a (16,15) semiconducting SWCNT (blue symbols), after a slight shift in energy and adjustment in strength. In the armchair nanotube, absorption from the continuum transitions is apparent in the high-energy wing. From the threshold of the continuum absorption (dashed line), we estimate an exciton binding energy of 50 meV. (b) Comparison of the theory (black solid line) for the optical transition in a metallic nanotube. The absorption can be decomposed into the dominant exciton contribution and a continuum contribution (green dashed lines). (After [4.233])

a hydrogenic model, the exciton binding energy was estimated to be ~ 300 to 400 meV for $0.6 < d_t < 0.9$ nm SWCNTs and showed a linear dependence on the inverse of the diameter [4.232]. Furthermore, the tubular nature of SWCNT crystal structure allows a magnetic field applied parallel to the tube axis to induce non-intuitive quantum phenomena. Such a magnetic field breaks time reversal symmetry and adds an Aharonov–Bohm phase to the electronic wavefunction, which mixes the lowest-energy bright and dark exciton states. In particular, a series of recent experiments [4.156, 157, 165–169] demonstrated that such a symmetry-breaking magnetic field can dramatically *brighten* the dark state. Namely, the PL intensity increases, or *brightens*, with magnetic field and the amount of brightening decreases with temperature. This phenomenon, magnetic brightening, can be understood as a consequence of interplay between the strong intervalley Coulomb mixing and field-induced lifting of valley degeneracy.

Contrary to the situation of semiconducting SWCNTs, excitonic properties of metallic SWCNTs have been poorly explored [4.186], although they are expected to provide a novel system for the study of electron–hole pairs in the presence of degenerate 1-D

electrons. Unlike *conventional* 1-D metals, the lowest van Hove singularity (VHS) peak in the conduction-band is unoccupied in metallic SWCNT, allowing one to create excitons into an interacting 1-D electron system by resonantly pumping the lowest 1-D VHS peak. The created excitons should show unique dephasing and energy relaxation dynamics, the correct understanding of which should provide significant new insight into many-body dynamics in femtosecond time scales. Screening does take place in metallic SWCNTs, but only weakly, allowing for exciton binding energies to reach 50 meV, as measured by direct optical absorption of a single metallic SWCNT [4.233], shown in Fig. 4.22. Unlike graphene, transitions in metallic SWCNTs cannot occur between the linear bands that form the Dirac cone at K and K' , as discussed earlier. Instead, like semiconducting SWCNTs, the lowest allowed transition occurs between the highest valence van Hove singularity the lowest conduction one. This transition is heavily modified by the large exciton binding energy creating Lorentzian-like transitions that are similar to the semiconducting SWCNTs. Since the absorption is from excitons and not a free plasmon resonance like most metals, metallic SWCNTs scatter the visible light that they do not absorb [4.234].

4.5 Transport Properties

Electronic transport properties of carbon nanotubes were studied intensively very soon after their discovery. A wide variety of CNT systems have been studied, including ropes, networks, and films. Numerous effects typical of polymer matrices, classical crystals, and disordered materials have been observed in these bulk

systems. Some of the key parameters governing transport are the sample quality and the nature and number of nanotube–nanotube and nanotube–electrode junctions. In this section, a brief presentation of nanotube films is given to illustrate the complexity induced by the combination of these parameters; the main part is dedicated

to individual nanotubes, where a better understanding has been achieved, to illustrate the strong distinction between metallic and semiconducting nanotubes and some of the most important parameters to describe their device operation.

SWCNT films or *mats* are formed by randomly or partially oriented *SWCNT* bundles. In some respects, such a network is similar to an amorphous metal system with conductive tubes or bundles as the metallic islands separated by energy or spacial barriers. As a result, the *DC* transport is primarily determined by intertube transport within bundles or interbundle transport, while the *1-D* intratube transport nature is buried [4.235].

The *DC* conductivity of *SWCNTs* is metallic at high temperatures, increasing linearly with decreasing temperature [4.236]. However, at lower temperatures, the *DC* conductivity reaches a maximum and starts to decrease with decreasing temperature. Such non-metallic behavior is usually explained by either variable range hopping (*VRH*) [4.237, 238] or fluctuation-induced tunneling (*FIT*) [4.239, 240]. But it is still not clear whether such behavior is mainly due to weak interbundle connections, localization by impurities, defects, or frozen semiconducting tubes within bundles [4.235]. Other experimental techniques such as magnetoresistance measurements [4.237, 238] and *AC* conductivity measurements [4.241, 242] are also used to explore the transport mechanism in *SWNT* films.

Studied as *individual nano-objects*, both metallic and semiconducting nanotubes have provided much insight and are still explored as both ideal one-dimensional mesoscopic systems [4.243–246] and potential building blocks for electronic applications [4.247–251]. Metallic nanotubes have charge carriers with very high mobilities near the Dirac point, and current densities as high as 25 μA can be carried by a single nanotube [4.252], making them much larger than copper for the same cross-section. Moreover, due to the strong Coulomb interaction in one-dimensional metals, electron–electron correlations become important and their properties become described by the Tommonaga–Luttinger liquid model [4.253]. On the other end, the chirality dependence of semiconducting nanotube band gaps have allowed to study many device properties ranging from single-electron transistors [4.254] to Schottky [4.255] and p-n diodes [4.251] and are showing a very high sensitivity to the environment or external excitations (optical, magnetic) expected to give rise, combined with their mechanical strength, to highly robust detectors.

In most of the numerous reports in the literature, individual nanotubes are directly contacted by two metallic electrodes and a third nearby electrode is used to apply an electrostatic field (Fig. 4.23), as proposed since the first transport measurements in 1997 and 1998 [4.243, 247–249]. This three-terminal (transistor) configuration allows the direct determination of the metallicity of the nanotubes (Sect. 4.2.2) by measuring the resistance or current-voltage characteristics of the device as a function of the potential applied through the third electrode (called gate). The detailed fabrication procedure varies a lot depending on the expected outcomes: devices are obtained by either depositing nanotubes from dispersions or directly growing them on a substrate; electrodes can be deposited on top of the nanotubes, or they can lie on top of them; typically the substrate is highly-doped silicon (which will be used as the gate electrode) over which a thermal oxide is grown (Fig. 4.23); as a consequence, the *SWCNT* can be suspended or directly in contact with the substrate.

Most basic electronic properties can be clarified by considering the effect of an external potential to the doping level of the nanotube, and the transport characteristics of a *1-D* system. This second aspect can be given by the Landauer formula of the two terminal resistance [4.256]. The two-terminal conductance of a *1-D* system, is given by

$$G = \frac{4e^2}{h} \sum_i \int \bar{T}_i(E) \left(-\frac{\partial f[(E - E_F)/k_B T]}{\partial E} \right) dE, \quad (4.6)$$

where the total conductance is given by the sum at the Fermi energy E_F of all subbands with index i of transmission $\bar{T}_i(E)$, and $f(E)$ is the Fermi distribution. The prefactor 4 is due to the subband spin and orbital degeneracies.

The modulation of the nanotube doping by the gate voltage can be obtained by considering the electrostatic equilibrium at a given gate potential. The carbon nanotube is capacitively coupled to the gate electrode and charges are injected in both of them. This charge injection will induce a change in the electrochemical potential of the nanotube through a density-of-states term [4.257, 258] and can be expressed as (for low source–drain voltage and neglecting temperature broadening)

$$E_F = eV_g - e^2 \frac{\int_0^{E_F} \rho(E) dE}{C_g}, \quad (4.7)$$

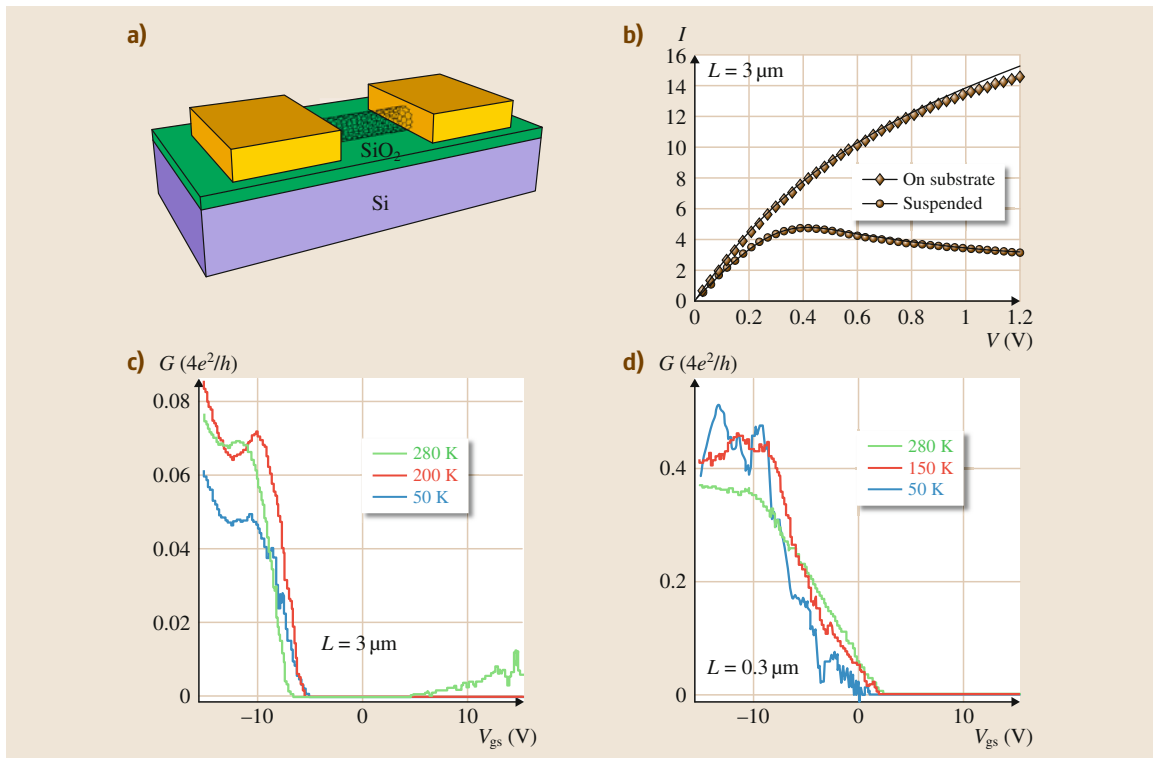

Fig. 4.23 (a) Schematic of the typical transistor configuration used to measure individual carbon nanotube transport properties. (b) $I(V)$ characteristic at high voltage of a long carbon nanotube device with comparison between a nanotube on substrate and suspended. (After [4.252]). (c) Conductance G (at low source-drain bias V_{ds}) versus gate voltage V_{gs} for a $3 \mu\text{m}$ long SWCNT device recorded at various temperatures. (d) G versus V_{gs} for a 300 nm long tube section on the same tube as for (c) at various T . ((c,d) after [4.245])

with V_g the potential applied between the gate and the source-drain electrodes, C_g the electrostatic (geometric) capacitance and $\rho(E)$ the density of states integrated from the center of the band gap (or the Dirac point) to the Fermi energy. In this specific expression, the Dirac point is assumed to be at $V_g(E_F = 0) = 0 \text{ V}$. However, in most devices, due to charge traps and doping from the oxide or impurities, an hysteresis in the gate dependence [4.259] and a threshold voltage ($V_g(E_F = 0) = V_{th}$) will appear [4.260, 261].

From these two equations, one can see that the conductance depends on the transmission of electrons through the whole device at the Fermi energy controlled by the gate voltage. Hence, different nanotubes will exhibit clear gate dependencies even at room temperature:

- Semiconducting nanotubes will exhibit field-effect transistors type behaviors with on/off ratios of many orders of magnitude, since there is no subband

available near E_F . They will exhibit diode type current-voltage characteristics. The most common reported behavior is unipolar with a p-doping of the nanotube attributed to adsorbates on the nanotube surface [4.249] (Fig. 4.23c,d) and effects from the substrate (or the electrodes); however, ambipolar devices are now commonly achieved [4.262].

- The small band gap carbon nanotubes will only show a small dip, since the band gap energy is comparable to the thermal energy and the tails of the Fermi distribution are within the valence or conduction band.
- Metallic nanotubes will only show very weak (or no) gate voltage dependence since they will be less sensitive to the gate voltage (due to finite density-of-states everywhere) and the number of subbands will remain constant over a large energy range; and they typically exhibit linear $I-V$ curves before saturation.

The various transport regimes described by (4.6) are governed by the transmission of the whole device including the tube, but also the contacts. The minimum conductance is then given by the ballistic regime where $\bar{T}_i(E) = 1$ and gives a quantized conductance of $G_{\text{bal}} = \frac{4e^2}{h}$ for each subband. This corresponds to a resistance of 6.5 k Ω . At room temperature, additional resistance is due to incoherent addition of nonperfect contact transmission and diffusive centers in the nanotube, this is the *classical regime*. At low temperature, coherent effects dominate and quantum dot regimes or localization effects develop; these regimes are referred as *quantum transport* or *mesoscopic regimes*. Ballistic resistance has been demonstrated for metallic carbon nanotubes up to room temperature [4.244, 263], whereas semiconducting nanotubes do not exactly reach this value [4.245, 263] (Fig. 4.23c,d).

Impressive progress has been made in the understanding and reduction of the contact contribution to the resistance. Different metals have been used to contact nanotubes with the most common being gold, titanium, palladium and platinum. A first barrier can form at the interface between the metal and the nanotube due to bad wetting of the nanotube in the metal; this interface will be governed by the cleanliness and contaminations of the interface and by the overlap between the metal-nanotube wavefunctions [4.28]. A low, ohmic contact resistance is typically obtained by using top electrodes made of palladium or gold and/or by annealing the device. Another route to achieve near perfect contacts consists in direct growth on top of the contacts [4.245], or using nano-welding (*burying* the nanotube in the contact). Moreover, in the case of semiconductors, even with a good interface a Schottky barrier can form depending on the band alignment [4.255, 264]. The matching of the metal and nanotube work function has been shown to provide a good approximation of this barrier height, although charge transfer at the interface must be considered for a precise understanding. These barriers have been shown to govern the field-effect properties of nanotube transistors and yield to a very high sensitivity of these devices to the environment. As an example, a good p-type contact will be obtained for a metal with a high work function, but a good interface is also necessary. As a consequence, titanium will be a bad choice due to its work function lying in the center of the nanotube band gap, but platinum also, due to a poor contact and the formation of additional barriers; whereas palladium will satisfy both conditions.

Obviously, the intrinsic resistance of the nanotube will also contribute to the overall measured value. In the

classical case, the two main contributions come from scattering by disorder and phonons. The origin of disorder is often complex to assign and scattering can be due to lattice defects (vacancies, impurities, ...), mechanical deformations and potential fluctuations induced by adsorbates and the substrate [4.261]. A backscattering mechanism can be distinguished between intervalley (from K to K') or intravalley scattering and will be associated with short-range and long-range disorder, respectively. It has been theoretically [4.261] shown that metallic nanotubes are insensitive to the first type of scattering and they exhibit lower intrinsic resistance than semiconducting nanotubes. Scattering will also occur with acoustic phonons at low source-drain bias. In metallic and clean (doped) semiconducting nanotubes the I - V curves are linear at low-bias; and mobilities higher than 100 000 cm²/(V s) and ballistic transport for short distance between contacts have been demonstrated [4.244, 252, 263]. At higher voltage, the resistance will start saturating due to interaction with optical phonons (around $\hbar\omega_0 \simeq 160$ meV) and the maximum current carried by a single tube will be as high as 25 μ A (Fig. 4.23b). For suspended nanotubes, a negative differential conductance can even be observed due to heating induced by hot phonons (Fig. 4.23b). This higher current limit can be overcome only for contact distances shorter than the optical phonon mean-free path around 10 nm [4.265].

At lower temperature, coherent addition of the scattering contributions and coherent transmission at the electrode interface must be considered. Moreover, the effect of confinement and electron-electron interaction becomes important and some of these effects might even need to be considered up to room temperature. A large variety of phenomena have been observed depending on the metallicity, the transmission at the contacts and the nature, density and strength of the scattering centers in the nanotubes. Detailed reviews provide an extensive description of such quantum phenomena from both the theoretical [4.28, 261] and experimental point of views; we can summarize some of the consensus achieved by dividing these mesoscopic results in three main effects:

- Correlated electrons in 1-D metals are not described by a Fermi liquid of weakly interacting fermions, but as a correlated ground state called a *Luttinger liquid*. Spin and charge propagate as two independent bosonic modes and different power law dependencies of the tunneling density of state and conductance are expected. This law will depend on

the bias voltage range, temperature, the nature of the contacts (to the end or the bulk of the nanotubes) and will depend on the Luttinger liquid parameter, $g \approx 0.22$ for SWCNTs [4.36, 266]. Although such measurements are difficult to assign univoquely, experimental power laws have been demonstrated to be consistent with theory [4.253, 267].

- When the presence of scatterers becomes too important, the mean-free path is given by static scatterers; as the temperature decreases the coherence length increases and coherent back-scattering takes place: this is the so-called *localization regime*. Both weak and strong localization can occur depending whether disorder or electron interactions dominate. Magneto-resistance measurements allow unique assignment of these regimes, and, in the case of individual SWCNTs, weak localization is intimately related to Luttinger liquid behaviors; this is not the case for small bundles or MWCNTs, where Fermi liquid behaviors are observed.
- When no (or very few, weak) scattering centers are present, the coherent response is dominated by the reflection and transmission at the contacts. The behavior can vary from *Coulomb blockade* [4.243, 247, 269], where nanotubes behave like single-electron transistors when contacts are transmit poorly, to *Fabry–Perot type* interferences [4.244, 263], where the system behaves like an electron waveguide when contacts are almost transparent. Both regimes are characterized by very strong oscillations of the conductance, as illustrated in Fig. 4.24. In the first case, the finite length of the nanotube induces a supplementary quantization of the wavevector and forms of a zero-dimensional system (right inset), while in the second case, constructive and destructive interferences of the wavefunction occur (left inset). Interestingly, in both cases, the induced wavevector quantization is given by $\Delta k = \pi/L$. The quantum dot regime exhibits more complex V_g and V_b dependency due to degeneracy lifting induced by the mutual interaction between added charges leading to spin-orbit coupling. Magnetoresistance measurements have been very useful to probe such effects in detail [4.269].

One of the current challenges in the field consists in exploiting the properties of single nanotube devices to

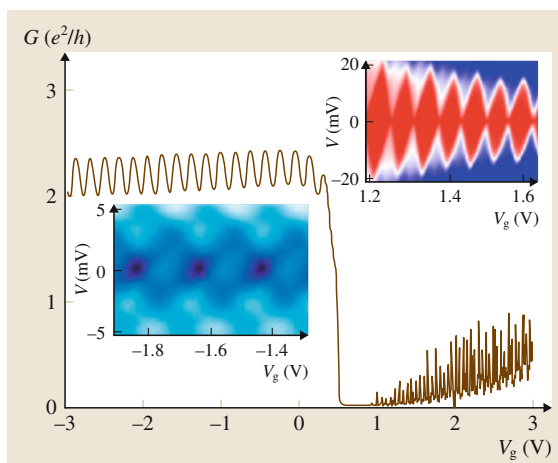

Fig. 4.24 Gate dependent conductance of a suspended, ultra-clean small band gap carbon nanotube at $T = 300$ mK. The almost transparent contacts in the p-doping regime exhibits a Fabry–Perot pattern. *Left inset*: shows conductance while varying bias and gate voltage (dark blue: $2e^2/h$, bright white: $4e^2/h$). In the *n* doping regime, Schottky barrier and lower transmission at the contacts induce a Coulomb blockade regime. *Right inset*: Coulomb diamonds. (After [4.268])

large-scale applications and much progress has been made in building more and more complex structures using individual nanotubes, and also controlling bulk samples by using for example aligned growth or chirality sorted films. These structures have been exploited in numerous configurations and for various applications. For example, large-scale logic and analog electronic structures, microwave and radio-frequency operation, proximity effects from superconducting or ferromagnetic electrodes have been demonstrated. It is also worth noticing that transport measurements have also been coupled with other experimental configurations and a very rich literature has also arisen regarding photovoltaic detection and electroluminescence, nano-electromechanical resonators, and scanning tunneling spectroscopies. All this has contributed to a deeper understanding of the mechanisms described above, but also demonstrated the wide range of potential applications of carbon nanotube especially for (mass or chemical) sensors and optoelectronics [4.8, 270].

4.6 Thermal and Mechanical Properties

Since their discovery, it has been expected that **SWCNTs** would have remarkable thermal and mechanical properties. This is because of the hexagonal arrangement of carbon atoms and the nature of the sp^2 carbon bond. We will first present a brief introduction to the basic thermal properties of carbon nanotubes and then describe their mechanical properties, where a much larger consensus has been achieved.

4.6.1 Thermal Properties

Specific Heat

The specific heat C_v of graphite arises from phonon and electronic contributions as

$$C_v = C_{ph} + C_{el}. \quad (4.8)$$

The phonon contribution to the specific heat can be calculated by

$$C_{ph} = \int_0^{\omega_{\max}} k_B \left(\frac{\hbar\omega}{k_B T} \right)^2 \frac{\exp\left(\frac{\hbar\omega}{k_B T}\right) \rho(\omega)}{\left[\exp\left(\frac{\hbar\omega}{k_B T}\right) - 1 \right]^2} d\omega, \quad (4.9)$$

where $\rho(\omega)$ is the phonon density of states and ω_{\max} is the highest phonon energy of the material. For $T \ll \Theta_D$ (where Θ_D is the Debye temperature), only acoustic phonon modes are populated. If an acoustic phonon mode in d -dimensions follows an $\omega \propto k^\alpha$ dispersion, then according to (4.9), the corresponding specific heat should obey $C_{ph} \propto T^{d/\alpha}$ [4.47].

Figure 4.25a highlights the low frequency phonon modes of **SWCNTs** [4.37]. All acoustic phonon modes show linear dispersion and high phonon velocities. For example, for a (10,10) tube, $v_{LA} = 24$ km/s, $v_{TA} = 9$ km/s, and $v_{twist} = 15$ km/s. Thus, for each acoustic phonon mode, C_{ph} shows a linear relation to temperature given by [4.271]

$$C_{ph} = \frac{\pi k_B^2 T}{\hbar v_{ph} \rho_m}, \quad (4.10)$$

where ρ_m is the linear mass density and v_{ph} is the phonon speed.

The electronic contribution to C_v can be evaluated by [4.271]

$$C_{el} = \Omega \int_0^\infty (E - E_F) \frac{df}{dT} N(E) dE, \quad (4.11)$$

where f is the Fermi–Dirac function and Ω is the d -dimensional volume. For undoped metallic **CNTs**, $N(E)$ is a constant below the first van Hove singularities which implies that C_{el} also linear with temperature for $T \ll \hbar v_F / k_B R$:

$$C_{el} = \frac{\pi k_B^2 T}{\hbar v_F \rho_m}, \quad (4.12)$$

where v_F is the Fermi velocity. According to (4.10) and (4.12), the ratio between C_{ph} and C_{el} is

$$\frac{C_{ph}}{C_{el}} \approx \frac{v_{ph}}{v_F} \approx 10^2. \quad (4.13)$$

As a result, the electronic contribution to the specific heat can be ignored. For an undoped semiconducting **SWCNT**, C_{el} is even smaller and should decay more rapidly with decreasing temperature. However, if the tubes are doped above the van Hove singularity, then C_{el} could be significantly enhanced.

Figure 4.25b shows the measured heat capacity of **SWCNTs** with a highlight of their low temperature behavior [4.272]. The temperature dependence is also compared with other carbon materials. Briefly, the heat capacity of **SWCNTs** is smaller than graphene due to the reduction of density of phonons by *subband* splitting (see Fig. 4.25a inset). On the other hand, it is higher than graphite, whose low frequency phonons are further quenched by graphite inter-layer interactions. However, this discrepancy is amended when **SWCNTs** are tightly bundled due to the inter-tube bundling effect (Fig. 4.6). The low temperature behavior of the heat capacity could be well fitted by taking into account this bundling effect and also the lowest subband mode contribution (Fig. 4.25c). The fitting parameters are also close to the theoretically calculated phonon spectrum.

Thermal Conductivity

In this section, we will only consider diagonal elements of the thermal conductivity matrix

$$\kappa_{zz} = \sum c v_z^2 \tau, \quad (4.14)$$

where c is the specific heat, v_z is the group velocity, τ the relaxation time of a given phonon state, and the sum is over all phonon states. For $T \ll \Theta_D$, the relaxation time is determined by scattering off impurities, defects, and sample boundaries, and is roughly constant. Therefore the low-temperature thermal conductivity should follow the same temperature dependence as the specific heat. But due to the weight factor $v_z^2 \tau$, certain phonon

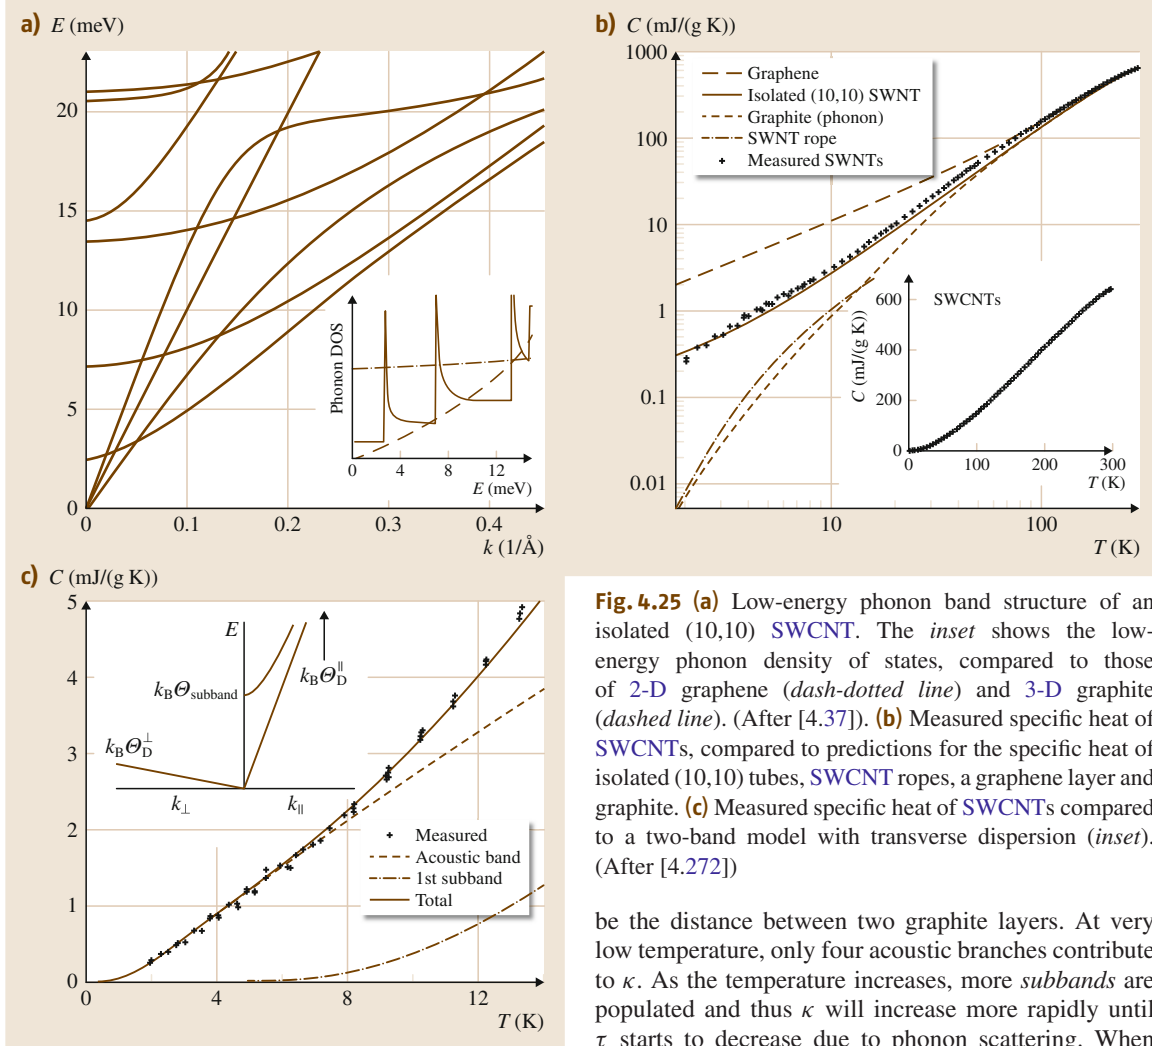

Fig. 4.25 (a) Low-energy phonon band structure of an isolated (10,10) SWCNT. The inset shows the low-energy phonon density of states, compared to those of 2-D graphene (dash-dotted line) and 3-D graphite (dashed line). (After [4.37]). (b) Measured specific heat of SWCNTs, compared to predictions for the specific heat of isolated (10,10) tubes, SWCNT ropes, a graphene layer and graphite. (c) Measured specific heat of SWCNTs compared to a two-band model with transverse dispersion (inset). (After [4.272])

modes with higher ν_z and τ should contribute more. κ is bounded by the 1-D ballistic transport limit. For each phonon mode, the quantum of thermal conductance is [4.47]

$$G_{\text{th}} = \frac{\pi^2 k_B T}{3 h}, \quad (4.15)$$

and therefore the effective thermal conductivity is

$$\kappa_{\text{eff}} = G_{\text{th}} \frac{L}{\pi d_t \delta d}, \quad (4.16)$$

where L is the length of the carbon nanotube, d_t is its diameter, and δd is the effective thickness that the phonon propagates over, which is usually assumed to

be the distance between two graphite layers. At very low temperature, only four acoustic branches contribute to κ . As the temperature increases, more subbands are populated and thus κ will increase more rapidly until τ starts to decrease due to phonon scattering. When $T \gg \Theta_D$, Umklapp scattering between zone boundary phonons will significantly reduce τ and consequently reduce κ [4.273]. So there should be a turning point in $\kappa(T)$, where it reaches its maximum. Since CNTs have a very high Debye temperature and their 1-D structure reduces Umklapp scattering due to deficiency in conserving momentum and energy, the turning point should be at a fairly high temperature.

In metallic or doped SWCNTs, electron systems also contribute to the thermal conductivity. Principally, the electronic thermal conductivity κ_{el} can be determined from electronic conductivity by the Wiedemann-Franz law

$$\frac{\kappa_{\text{el}}}{\sigma} \approx L_0, \quad (4.17)$$

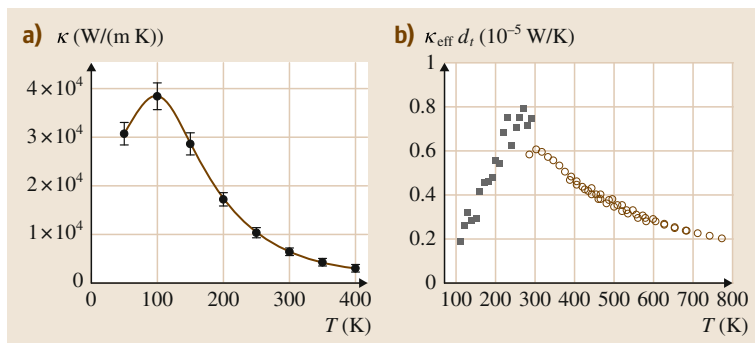

Fig. 4.26 (a) Calculated thermal conductivity of an isolated (10,10) SWCNT, as a function of temperature. (b) Measured diameter-adjusted thermal conductivity ($\kappa_{\text{eff}} d_t$, see (4.16)) of an isolated SWCNT, as a function of temperature. Since the diameters of the tubes range from 1 to 3 nm, the maximum value of kappa is several thousands W/(m K) (■: Yu et al. [4.273]; ○: this work). (After [4.274])

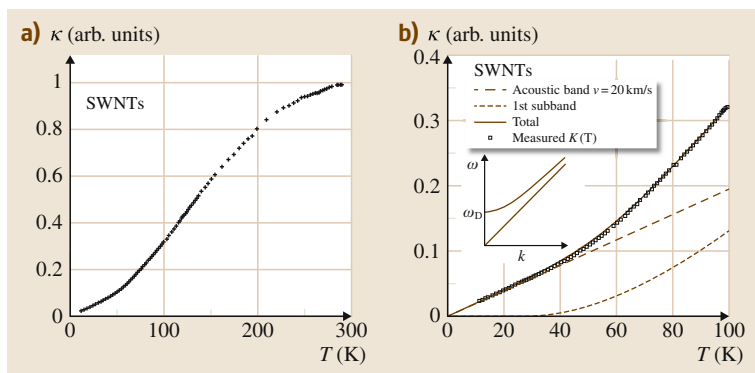

Fig. 4.27 (a) Thermal conductivity of a bulk sample of SWNTs below room temperature. (b) Highlight of the low temperature part fitted by two-band model. (After [4.275])

where the Lorenz number $L_0 = 2.45 \cdot 10^8 (\text{V/K})^2$ and σ is the electronic conductivity. The estimated κ_{el} is usually one or two orders of magnitude smaller than κ_{ph} and therefore can be ignored in most cases.

As shown in Fig. 4.26a the thermal conductivity of SWCNT has been predicted as high as 40 000 W/(m K) at its maximum and 3600 W/(m K) at room temperature [4.274]. On the other hand, the measured κ peaks around one order of magnitude lower a few thousandths of a watt per millikelvin W/(m K) as shown in Fig. 4.26b [4.276, 277], probably due to imperfections or short tube length [4.278]. When tubes are bundled or formed into a CNT network, κ will decrease strongly depending on the sample's morphology. The reduction may be attributed to a quench of phonon modes by intertube interactions, analogous to the effect on C_{ph} . This effect should be more significant for well-aligned CNT fibers or MWCNT devices [4.279]. Another reason is the weak transport at tube–tube junctions. It has been predicted that in a random network, κ would obey [4.280]

$$\kappa \sim \rho^2 L^2, \quad (4.18)$$

where ρ is the density of tubes in the network. This opens the possibility to tune the thermal conductivity of a SWCNT device from a good thermal conductor to a good thermal insulator [4.281].

Figure 4.27 shows a measured κ as function of temperature for a SWCNT network [4.275]. In this case, the effect of the intertube junction on κ is treated as a reduction of the phonon relaxation time τ . Consequently, the turning point of κ shifts to a higher temperature while its temperature dependency still reflects the 1-D nature of a CNT. The $\kappa(T)$ curve could be fit by considering the four acoustic phonon modes and the first subband mode (Fig. 4.27b). However, the fitting parameters are slightly different from those by fitting to heating capacity. The difference may be attributed to the weight factor $v^2 \tau$ in κ .

4.6.2 Mechanical Properties

SWCNTs lack the multiple cylindrical nesting of MWCNTs and are expected to be stiffer due to curvature effects [4.282]. Over the past couple of decades, SWCNTs have attracted a considerable amount of interest owing to their extraordinary mechanical properties,

such as their ability to sustain large deformations, their excellent stiffness, and high strength. Additionally, most conventional synthesis techniques result in **SWCNTs** arranged in ropes with a close-packed stacking, thus forming high performance self-assembled fibers on the nanoscale.

Elastic Properties

Overney et al. were the first to report on the structural rigidity of carbon nanotubes [4.284]. The authors used an empirical Keating Hamiltonian with parameters determined from first principles in order to model **SWCNTs** consisting of 100, 200, and 400 atoms. It was later pointed out by *Treacy* et al. that their results implied a Young's modulus in the range of 1.5–5.0 TPa [4.285]. *Lu* performed an extensive study of the elastic properties of **SWCNTs** (Table 4.1) and **SWCNT** ropes using an empirical force constant model [4.283]. The Young's modulus, E , for the materials was extracted from the second derivative of the ab initio strain energy with respect to the axial strain, $\partial^2 E / \partial \epsilon^2$. The tensile Young's modulus (≈ 1 TPa, a value which is in good agreement with the C_{11} elastic constant of graphite) and the torsion shear modulus of individual **SWCNTs** were found to be comparable to that of diamond and that of a graphitic sheet, while the bulk modulus was found to be smaller. Their elastic moduli were shown to be insensitive to structural details such as the chirality and radius. One must bear in mind that in order to deduce properties such as **SWCNT** Young's modulus, it is re-

quired to adopt a convention for the effective nanotube thickness. *Lu* chose the interlayer separation of graphite (0.34 nm, now a widely accepted convention) as the **SWCNT** wall thickness in his calculations. Assuming the extent of π orbitals (≈ 0.066 nm) to be the thickness, as *Yakobson* et al. had proposed earlier, can result in rather spectacular values of the **SWCNT** Young's modulus (≈ 5 TPa) [4.286]. *Lu's* study of **SWCNT** ropes, each assumed to be composed of 100–500 armchair **SWNTs** of uniform size arranged in hexagonal order, found them to be soft along the basal plane but very stiff along the axial direction. Their Young's moduli (average ≈ 0.6 TPa) were found to be about one-half that of diamond, values that decreased with nanotube radius. An alternate method that was based on the energy per-surface area rather than per-volume was used to deduce the **SWCNT** Young's modulus [4.287]. The authors used a nonorthogonal tight-binding scheme for their calculations and reported a surface Young's modulus of 0.42 TPa-nm (1.2 TPa) with only a slight dependence on diameter for **SWCNTs** with a diameter > 0.7 nm.

Interestingly, while **SWCNTs** can be highly rigid in the axial direction (as is evident from the high tensile Young's modulus values), they can experience considerable structural instability under compression, torsion, or bending in the radial direction [4.288]. *Yakobson* et al. modeled the buckling of **SWNTs** exposed to axial compression, with the atomic interaction modeled using the Tersoff–Brenner potential [4.289, 290]. They found

Table 4.1 Elastic coefficients and moduli of selective single-walled nanotubes. (n, m) are the chiral indices, R is the radius in nm, C_{11} and C_{33} are the elastic constants along the basal plane and the axial direction, respectively. B , Y , M are bulk, Young's, and shear moduli in units of TPa and ν is the Poisson ratio. Experimental values for the graphite and the diamond are listed for comparison. (After [4.283])

that nanotubes subject to large deformations reversibly switched into four different morphological patterns with each one corresponding to an abrupt release of energy and a singularity in the strain energy versus strain curve (Fig. 4.26). The authors' simulations of bending and torsion resulted in **SWCNT** cross-section collapses and similar observations of changes in energy with the increase in bending angle and azimuthal angle, between the tube ends, respectively. Cross-section collapses and flattening can also occur in **SWCNT** ropes owing to van der Waal's attractive forces between the tubes. Tersoff and Ruoff studied the deformation pattern of **SWCNTs** in ropes and concluded that rigid tubes with diameters < 1 nm deform insignificantly while those with diameters > 2.5 nm flatten against each other thus forming a honeycomb-like structure [4.291].

Strength and Plasticity

Quantum mechanical calculations predict that defect-free single-walled carbon nanotubes possess tensile strengths greater than 100 GPa (i.e., close to the theoretical strength viz. $E/10$ GPa) and failure strains as high as 15–30% depending upon chirality [4.293, 294]. Yakobson et al., used molecular dynamics (MD) simulations to perform high-strain-rate tensile tests (in the range of 100 MHz) on **SWCNTs** and found that stretching simply elongated the hexagons in the tube walls, until at the critical point an atomic disorder suddenly nucleated: one or a few C–C bonds broke almost simultaneously, and the resulting *holes* in the tube walls became crack precursors. While the fractures propagated very quickly along the circumference of the tubes, the nanotubes themselves did not break completely in half but were separated into two parts connected by a monoatomic carbon chain [4.288]. Under compression, classical MD simulations have shown a **SWCNT** to also be remarkably resilient, sustaining strains as high as 15% with no signs of brittleness, plasticity, or atomic rearrangements [4.295].

Theoretical predictions, however, have constantly emphasized the important role played by defects, the loading rate, and temperature on the strength of a **SWCNT** [4.296]. Defects often become incorporated into the **SWCNT** structure during purification or dispersion. Also, the mode of **CNT** synthesis plays an important role in determining the nature and distribution of defects, with low temperature catalytic chemical vapor deposition (CVD) grown nanotubes typically having a more defect laden structure when compared to nanotubes grown via other techniques such as laser vaporization and arc discharge (AD). The presence of

Fig. 4.28 Stone–Wales (S–W) transformations of an equatorially oriented bond into a vertical position creates a nucleus of relaxation (*top left corner*). It evolves further as either a crack (*brittle fracture route, left column*) or as a couple of dislocations gliding away along the spiral slip plane (*plastic yield, top row*). In both cases only S–W rotations are required as elementary steps. The stepwise change of the nanotube diameter reflects the change of chirality (*bottom right image*). (After [4.292])

defects on the nanotube wall can considerably degrade the strength of a **SWCNT**. Belytschko et al. observed a drop in the failure stress from 93 GPa to 74 GPa upon the incorporation of a single atom defect on a zigzag **SWCNT** wall. The failure strains were also found to drop from 15.5% to 10% [4.293]. Sammalkorpi et al. used MD simulations to study how vacancies affect the Young's modulus and tensile strength of **SWCNTs** [4.297]. They found that while the Young's modulus depended weakly on the vacancy concentration (a relatively high defect density of one vacancy per 50 Å resulted in about a 3% decrease in the Young's modulus), the **SWCNT** tensile strength could degrade by $\approx 40\%$ (actual value chirality dependent) if vacancies were present on their walls.

With regard to the deformation of **SWCNTs** in static or slow tension conditions, an interesting phenomenon

was uncovered by quantum molecular dynamics simulations and dislocation theory: a mechanical relaxation step that occurs via a bond rotation known as a Stone–Wales (S–W) transformation (Fig. 4.28) [4.298]. It leads to the formation of the lowest energy defect, a cluster of two pentagons and heptagons 5/7/7/5 on the SWCNT wall. In a lattice of hexagons this represents a dislocation dipole, which explains its formation under high tension. At high temperatures, 5/7/7/5 defects in SWNTs of a certain chirality, can separate into two 5,7 pairs that glide away from each other in a spiral path, leaving in their wake a plastically deformed nanotube with an altered chirality. In contrast, a competing mechanism of evolution, which does not require thermal activation, occurs at a high strain level as a sequence of direct brittle bond-breaking steps leading to formation of disordered cracks and large open rings, which results in the brittle failure of a SWCNT (Fig. 4.28) [4.292, 299]. Thus, while all SWCNTs behave in a brittle fashion at high strains and low temperatures, at high temperatures and low strains, SWCNTs of a certain chirality can be completely or partially ductile. This has been observed in a (10,10) armchair nanotube with a 5/7/7/5 defect under axial tension. At a strain value close to 15% and temperature of about 1300 K, nucleation of large open rings occurred (brittle relaxation), while at a strain value $\approx 3\%$ and at a temperature of about 3000 K, 5/7 defect motion resulted in plastic flow [4.300]. It has been suggested that an axially compressed SWCNT would also deform plastically via S–W defect based mechanism [4.292]. Interestingly, Srivastava et al., who employed a quantum generalized tight binding molecular dynamics (GTBMD) scheme to study SWNTs under compression, observed an alternate mechanism of plastic deformation in which SWCNT bonding geometry collapsed from a graphitic sp^2 to a localized diamond-like sp^3 reconstruction [4.301, 302]. The computed critical strain for such a collapse for a (8,0) zigzag SWNT was $\approx 12\%$, a value considerably lower than the elastic limit computed using classical MD simulations (Fig. 4.29).

Mechanical Characterization

Owing to their small size and the magnitude of the forces involved, the mechanical characterization of individual SWCNTs is extremely challenging. There are thus only a handful of reports that deal with characterization of individual SWCNTs, with many of them relying on the electrical breakdown of MWCNTs for SWCNT generation. However, numerous studies fo-

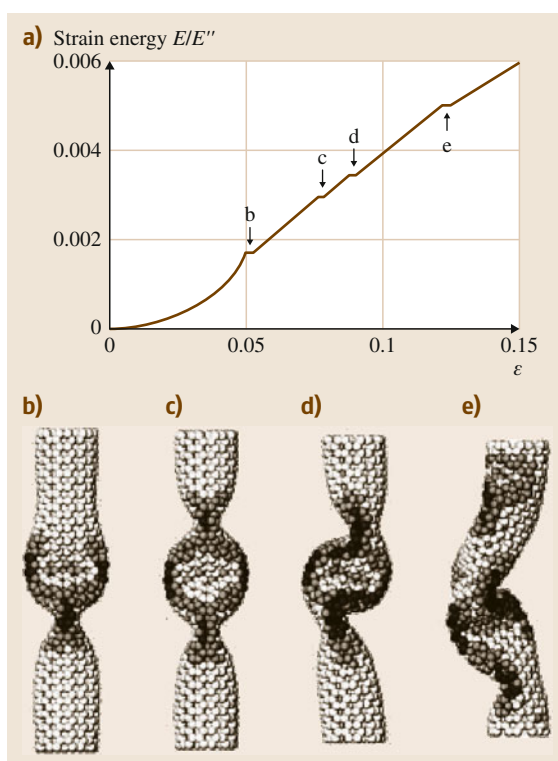

Fig. 4.29a–e MD-simulated nanotube of length 6 nm, diameter 1 nm, and armchair helicity (7,7) under axial compression. The strain energy displays four singularities **b, c, d, e** as shown in strain energy (normalized to its second derivative) versus strain (ϵ) curve corresponding to shape changes (**a**); at $\epsilon = 0.05$ the cylinder buckles into the pattern (**b**), displaying two identical flattenings, *fins*, perpendicular to each other. Further increasing strain enhances this pattern gradually until at $\epsilon = 0.076$ the tube switches to a three-fin pattern (**c**), which still possesses a straight axis. On buckling sideways at $\epsilon = 0.09$ the flattenings serve as hinges, and only a plane of symmetry is preserved (**d**). At $\epsilon = 0.13$ (**e**) an entirely squashed asymmetric nanotube. (After [4.286])

cus on the properties of SWCNT ropes. Using an atomic force microscope (AFM) based deflection technique, Salvétat et al. measured the vertical deflection of SWCNT ropes bridging holes on a porous alumina membrane (Fig. 4.30) [4.303]. The ropes were modeled as beams, with a term describing sliding between tubes (shear) comprising the ropes being included in the expression for mechanical deformation

$$\delta = \delta_B + \delta_S = FL^3/192EI + f_s FL/4GA,$$

Fig. 4.30 (a) AFM image of a SWCNT rope adhered to the polished alumina ultrafiltration membrane, with a portion bridging a pore. (b) The AFM is used to apply a load to the nanobeam and to determine directly the resulting deflection. (After [4.303])

where F is the concentrated load, δ_B and δ_S are the deflections due to bending and shear deformation respectively, L is the suspended length, E is the elastic modulus, f_s is the shape factor (equal to 10/9 for a cylindrical beam), G is the shear modulus, I is the second moment of area of the beam and A is the cross-sectional area. Deflections of small diameter long ropes, for which shearing was assumed to be negligible, were used to compute Young's modulus (measured to be about 1 TPa), while the deflection of thick ropes was used to compute the intertube shear modulus G measured as ≈ 1 GPa. Walters et al. also studied the elastic properties of freely suspended SWCNT ropes by inducing large elastic strains using an AFM tip operating in the lateral force mode [4.304]. By modeling the stretched ropes as elastic strings (instead of beams), the authors were able to derive an expression for the force F exerted on the tube by the AFM tip

$$F = 2T \sin(\theta) = 2T \frac{2x}{L} \approx \frac{8kx^3}{L_0},$$

where T is the tension in the string, L_0 its equilibrium length, k the spring constant, and x the lateral deflection in the middle. Assuming a Young's modulus of 1.25 TPa for SWCNTs, they deduced that close-packed

nanotube ropes would have a yield strength exceeding 45.67 GPa (corresponding to a 5.8% strain). Yu et al. subjected 15 SWCNT ropes to tensile loading using a nanostressing stage (two opposing AFM tips) operated inside an SEM chamber [4.305]. Force versus strain data were obtained for 8 ropes, with the highest strain value observed being 5.3%. By examining the fragments left on the AFM tips post failure, the authors deduced that only the SWCNTs along the periphery of the ropes were load bearing. They were thus able to ascertain the average breaking strength of SWNTs along the perimeter of each rope, viz. 13 to 52 GPa. The corresponding Young's moduli were determined to be in the range of 320 to 1470 GPa. The mechanical properties of SWCNT bundles in compression were studied by Chesnokov et al., who subjected them to quasi-hydrostatic pressure using a piston-cylinder setup. The bundles were found to undergo a reversible deformation up to a pressure of 3 GPa [4.306]. Tang et al. used a diamond anvil cell to subject SWCNT bundles to hydrostatic pressure and observed that the SWCNTs were linearly elastic up to 1.5 GPa at room temperature. The volume compressibility, measured via in situ synchrotron x-ray diffraction, was determined to be 0.024 GPa^{-1} [4.307].

Krishnan et al. estimated the stiffness of individual SWCNTs by observing their freestanding room temperature vibrations in a TEM [4.308]. The nanotube lengths and tip vibration amplitudes were estimated directly from the digital micrographs. The nanotubes were modeled as stochastically driven resonators (i.e., they were assumed to be vibrating beams) and their Young's moduli estimated from their Gaussian vibrational profile whose standard deviation is given by

$$\sigma^2 = 0.8486 \frac{L^3 k_B T}{YWG(W^2 + G^2)},$$

where L is the cantilevered beam's length (SWNT length), G is the graphite interlayer spacing, W is the SWCNT diameter, T the temperature and Y the Young's modulus. Micrographs of 27 nanotubes in the diameter range 1.0–1.5 nm were measured to yield an average Young's modulus of $1.3 + 0.4 / - 0.6$ TPa. Wang et al. directly tested the mechanical response of SWCNTs by subjecting them to tensile loads using an AFM within a TEM setup [4.309]. The SWCNTs for the experiments were formed in situ by subjecting MWNTs to large voltage biases. The tubes were found to exhibit fracture strengths ranging from 25 to 100 GPa. SWCNTs with relatively higher strength possessed visibly perfect

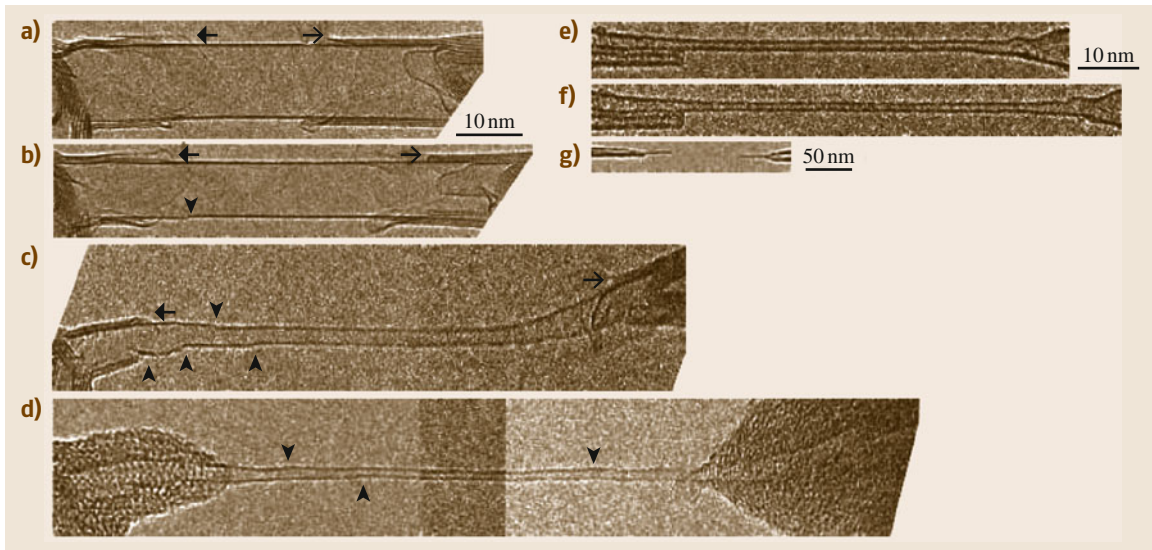

Fig. 4.31 In situ tensile elongation of individual SWNTs viewed in a HRTEM. (a–d) Tensile elongation of a SWNT under a constant bias of 2.3 V (images are all scaled to the same magnification). Arrowheads mark kinks, arrows indicate features at the ends of the nanotube that are almost unchanged during elongation; e.g., tensile elongation of a SWCNT at room temperature without bias ((e–g) are scaled to the same magnification). (After [4.310])

shell structures while the significant strength reduction in low-strength samples was attributed to clearly identifiable shell structural defects. Huang et al. observed *superplasticity* in a SWCNT (Fig. 4.31) [4.310]. The nanotube was subjected to a tensile load and at failure, found to be 91 nm long, showing an elongation of 280% with its diameter reduced 15-fold, from 12 to 0.8 nm. Since the deformation occurred at a bias of about 2.3 V,

the temperature in the middle of the SWCNT was estimated to be more than 2000 °C. This superplastic deformation was assumed to be the result of the nucleation and motion of kinks (possibly 5/7 pairs) as well as atom diffusion. In contrast, tensile-pulling experiments conducted at room temperature with no bias showed in SWCNTs failing at a tensile strain of less than 15%.

4.7 Concluding Remarks

Single-walled carbon nanotubes have been extensively studied and immense progress has been made in their basic understanding, demonstrating the potential of nanoscience in general. A good understanding of their basic properties has been reached, but direct evidences of some fundamental processes are still lacking; for example, spin-charge separation expected in Luttinger liquids.

The feasibility of nanotube applications lies directly between basic and technical questions. For example, nanotube photodetectors and emitters (or even lasers) would be of great tunability and could potentially cover large wavelength ranges. Efforts are being made to obtain purer, single chirality semiconductors material in large quantities, and to understand the mechanisms limiting their light emission.

Multi-Walled Carbon Nanotubes

Ákos Kukovecz, Gábor Kozma, Zoltán Kónya

Multi-walled carbon nanotubes (MWCNTs) are elongated cylindrical nanoobjects made of sp^2 carbon. Their diameter is 3–30 nm and they can grow several cm long, thus their aspect ratio can vary between 10 and ten million. They can be distinguished from single-walled carbon nanotubes on the basis of their multi-walled Russian-doll structure and rigidity, and from carbon nanofibers on the basis of their different wall structure, smaller outer diameter, and hollow interior. This chapter introduces MWCNT synthesis methods, discusses the chemistry and properties of multi-walled carbon nanotubes, and gives examples of their application. References to single-walled carbon nanotubes (SWNT) are kept at a minimum.

Multi-walled carbon nanotubes (MWCNTs) are elongated hollow cylindrical nanoobjects made of sp^2 carbon. Their diameter is 3–30 nm and they can grow several cm long, thus their aspect ratio can vary between 10 and ten million. The wall thickness of a MWCNT is fairly constant along the axis, and therefore the inner channel is straight. This channel is not directly accessible from the outside because the ends of perfect MWCNTs are capped by half fullerene spheres; however, it can be accessed by opening the nanotube using, e.g., oxidation, milling or ion beam treatment. MWCNT-specific reviews have been written by Forró and Schonenberger [5.1], Andrews et al. [5.2], and more recently by Lehman et al. [5.3].

The credit for discovering multi-walled carbon nanotubes is given to Sumio Iijima, who in 1991 re-

ported on carbon microtubulii found as by-products in the Krätschmer electronic arc discharge reactor used for fullerene synthesis.

Multi-walled carbon nanotubes can be distinguished clearly from single-walled and double-walled carbon nanotubes on the basis of (i) their larger diameter and (ii) their Raman spectrum. The distinction between MWCNTs and carbon nanofibers relies on the well-defined structure of carbon nanotubes: any elongated carbonaceous object with diameter below ~500 nm that does not feature a carbon nanotube structure is a carbon nanofiber (CNF). In principle, a multi-walled carbon nanotube consists of as many giant molecules as the number of its walls, and each molecule is as long as the nanotube itself. On the other hand, CNFs consist of entities (graphitic platelets) significantly smaller than

Fig. 5.1 (a) Typical appearance of as-synthesized multi-walled carbon nanotubes macroscopically and (b) in a high-resolution TEM image

the fiber itself, held together by secondary bonding forces and arranged in various ways including stand-

ing columns, herring-bone structures with and without a hollow inner channel, and even spirals.

Graphite is a three-dimensional (3-D) material consisting of several two-dimensional (2-D) layers (graphene sheets) of hexagons of sp^2 carbon atoms arranged into a hexagonal honeycomb lattice. Single-walled carbon nanotubes (SWCNTs) can be derived by rolling up a long, thin strip of hexagons cut out of a graphene sheet to make the opposite long edges meet.

Multi-walled carbon nanotubes are assemblies of several SWCNTs arranged in a coaxial Russian-doll structure, each single-walled nanotube corresponding to one wall of the MWCNT. The wall-to-wall distance is 0.340 nm, slightly larger than the sheet-to-sheet distance in graphite (0.335 nm) [5.4] (Fig. 5.1). A major difference between MWCNTs and SWCNTs is that the former are stiff, rigid, rod-like structures whereas single-walled carbon nanotubes are flexible.

5.1 Synthesis

Although the original discovery of multi-walled carbon nanotubes (MWCNTs) was recently credited [5.5] to *Radushkevich* and *Lukyanovich* [5.6] in 1952, it is without doubt that the current *carbon nanotube boom* in materials science was initiated by the 1991 paper of *Iijima* on *helical microtubules of graphitic carbon* [5.7] and the subsequent discovery of single-walled nanotubes (SWNTs) in 1993 independently by *Iijima* and *Ichihashi* [5.8] and *Bethune et al.* [5.9].

Multi-walled and single-walled carbon nanotubes can be prepared using the same general techniques tuned towards one or the other tube type. A broad variety of synthesis methods have been developed in the past 20 years, and now MWCNT synthesis is a well-established process that has successfully been scaled up to a commercial level. Catalytic chemical vapor deposition (CVD) is the most feasible and widespread synthesis method today; however, arc discharge and laser ablation must also be mentioned.

5.1.1 Arc Discharge

Arc discharge carbon nanotube synthesis reactors operate by igniting an electric arc (60–100 A across a potential drop of 25 V) between two graphite electrodes in a gaseous atmosphere (typically an argon/hydrogen mixture). The temperature in an electric discharge may reach as high as 4000 °C, and a plasma is formed. The electrode material evaporates and con-

denses as filamentous carbon product on the cathode which contains carbon nanotubes. Using this method, successful fullerene (1990) [5.10] and carbon nanotube synthesis (1991) [5.7] were performed.

Lozovik and *Popov* [5.11] divided the operation mode of electric discharge systems into a noisy and a quiet one. Continuous transition between the two modes can be simply regulated by changing the current density. It was found that high current density and low inert gas pressure results in the formation of fullerenes, while for low current density and high pressure, nanoparticles and nanotubes are predominately formed. *Ebbessen* and *Ajayan* [5.12] developed the technique to make it suitable for large-scale production. Helium is run through the reactor at a controlled rate and pressure. The anode graphite rod may contain a drilled hole filled with metal catalyst. This is necessary for arc discharge production of single-walled carbon nanotubes, but the right catalyst can promote MWCNT formation as well.

The crystallinity of arc-discharge-synthesized MWCNTs can be improved by increasing the hydrogen content of the chamber gas, or doing the synthesis in liquid nitrogen [5.13] or in a magnetic field [5.14]. The productivity of the method can be improved by optimizing the quenching process [5.15, 16] or by applying the plasma-rotating arc discharge technique [5.17].

Advantages of the arc discharge method are its simplicity and versatility in terms of carbon source material

and catalyst. Its major disadvantages are the high energy consumption, low potential for industrial up-scaling, and the necessity for postproduction purification steps. The product formed on the cathode is composed of various types of carbonaceous matter, including nanotubes, fullerenes, carbonaceous nanoparticles, and catalyst.

5.1.2 Laser Ablation

Laser ablation is the method that started the nanocarbon revolution back in the 1980s. Curl, Kroto, and Smalley used this process to synthesize fullerenes in their pioneering experiment. When a laser beam is used for evaporating a carbon target, generally containing transition metals as catalyst component, similar processes take place as in arc discharge [5.18]. In a typical laser ablation experiment, the second harmonic of a Nd:YAG laser pulse is focused onto a graphite target containing 1–2 at.% catalyst metal [5.19–21]. The target is kept in an inert gas flow, and the system is heated to 800–1400 °C by an electric furnace. The laser evaporates the target into a plasma in which carbon nanotubes are formed. The produced nanotubes are swept by the inert gas stream onto a cold finger collector and removed periodically from the reactor. Laser ablation is unsuitable for mass production. On the other hand, it yields very high-quality nanotubes, and therefore it has been the synthetic method of choice for many fundamental studies.

5.1.3 CCVD Methods

CCVD stands for *catalytic chemical vapor deposition*. Although CVD is also a valid term in general, CCVD should be preferred when discussing carbon nanotube synthesis because all CVD-based CNT production methods rely on a catalyst. In a general CCVD synthesis, a volatile carbon source (hydrocarbons, alcohols, CO, etc.) is introduced into a reactor, where it is decomposed on a suitable catalyst (transition metal) surface and its carbon content is recrystallized in carbon nanotube form. Both single-walled and multi-walled carbon nanotubes can be produced by CCVD. The mechanisms for CCVD MWCNT growth have been reviewed by Bajwa et al. [5.22].

CCVD can be realized in many practical designs. The catalysis can be homogeneous (carbon source and catalyst are both volatile) or heterogeneous (catalyst is supported in the solid phase). The metal catalyst can be pre-made (metallic nanoparticles deposited on the support) or can form in situ from a volatile organometal-

lic compound such as ferrocene in a homogeneous catalytic reaction or from thin metallic films or impregnated metallic compounds in heterogeneous catalytic synthesis. Energy for the carbon source decomposition can be supplied as heat, microwaves or plasma. Thermal CCVD methods utilize either conventional heating methods such as a tube furnace or in situ heating as in hot-filament CCVD synthesis.

Advantages of the CCVD method include cost efficiency, scalability, continuous operation, and relatively low (500–800 °C) operating temperature. Combined with the ability to yield aligned nanotubes that grow in predesigned patterns only, this latter property renders CCVD a good candidate for integration with the silicon-based semiconductor industry. Notable disadvantages of the CCVD method are the lower quality (more defects in the wall structure and more carbonaceous contamination deposit) of the synthesized nanotubes and the necessity for a postsynthetic purification step in which the catalyst and/or catalyst support are removed.

The first successful experiments on the preparation of multi-walled nanotubes (MWNTs) by and Ivanov [5.23] were followed by hundreds of modified or new procedures. On the basis of these experiments, several fundamental principles were concluded. In most cases the syntheses are carried out at high temperature, applying a stream of carbon source diluted with inert compounds such as nitrogen, argon, etc. The experimental setup consists of a high-temperature oven in which the catalysts are placed onto a highly resistant ceramic or metal plate.

The nature and yield of the deposit obtained in the reaction are controlled by varying different parameters such as the nature of the metals and the supports, the hydrocarbon sources, the gas flows, the reaction temperature, the reaction time, etc. By selecting the proper conditions, both the physical (e.g., length, shape, diameter) and chemical properties (e.g., number of defects, graphitization) of the MWNTs can be designed in advance. For catalyst preparation, various methods are applied, such as impregnation, ion exchange, and mechanical grinding of the support and the metal components. The activity of catalyst samples prepared in different ways shows dependence on the nature of the catalyst support (silica of different pore diameter, zeolites of various structures) and on the pH of the solution used during the synthesis of the catalyst samples. Supported Co [5.24], Ni [5.25], and Fe [5.26] catalysts were found to be the most active in CVD. When other elements (e.g., Cu, Cr, Mn) are used, only a negligible amount of carbon nano-

tubes (NTs) is formed. As far as the catalyst support is concerned, its quality is of considerable importance. While Si-, Mg-, and Al-containing materials (silica, alumina, zeolites, magnesia) prove to be applicable as supports, the different forms of carbon (graphite, activated carbon) are not suitable for NT production. These results suggest that the support has a peculiar role in the reaction. The hydrocarbons most frequently used are acetylene, ethylene, and benzene because of their high carbon content. It was also shown that, generally, increasing the reaction time results in the formation of larger amounts of amorphous carbon due to deactivation of catalytic sites. Determining the optimal reaction temperature is a very complicated task since several requirements come into conflict: while high temperature favors proper graphitization, the homogeneous pyrolysis of the hydrocarbon becomes excessive above a certain temperature depending on the carbon source used. Moreover, the metals and supports demand different temperature ranges.

Nanotubes of helical shape have been produced using particular catalyst preparation methods [5.27, 28]. Silica and alumina supported Co catalysts proved to give a large amount of helical tubes in the decomposition of acetylene at 700 °C [5.29]. According to results obtained over catalysts prepared by impregnation, the quality of the tubes strongly depends on the pH of the initial solution and on the pretreatment applied during catalyst preparation. Those samples which contain acidic centers on the surface show low activity. Formation of carbon nanotubes is observed over catalysts produced from solutions of pH ≥ 7 . Although catalyst activity increases in parallel with the basicity of the solution, selectivity towards helical carbon nanotubes increases suddenly when the catalyst surface has neutral character. The presence of acidic OH groups on the silica support probably hinders carbon nanotube formation and side-reactions which do not involve carbon deposition become dominant [5.30].

With further pH increase, the amount of spiral nanotubes becomes significantly higher. A possible explanation for this phenomenon is that the solubility of Co-acetate is good at low pH, and therefore particles formed on the silica surface are symmetric. Consequently, the catalytic centers are symmetric too. With increasing pH, precipitation of Co(OH)_2 begins, and some particles get onto the surface of the catalyst support in a solid, probably asymmetric form. Presumably, these asymmetric particles contain regions of different catalytic activity, which can help in forming carbon nanotubes of helical shape. Note that the formation of

spiral carbon nanotubes was observed only in catalytic processes [5.31].

It is important to note here that, according to our current understanding of the catalyst state in carbon nanotube growth, a liquid-catalyst phase favors CNT growth whereas a solid catalyst phase hinders it [5.32]. Since a liquid surface is not asymmetric, the role that any asymmetric catalyst particle could play in spiral carbon nanotube growth is still heavily debated.

Arrays of aligned multi-walled nanotubes have been synthesized for use in flat-panel display applications. Thess et al. [5.18] succeeded in producing more than 70% of single-walled nanotubes by condensation of a laser-vaporized carbon–nickel–cobalt mixture at 1200 °C. In parallel, iron particles embedded in mesoporous silica were used for large-scale synthesis of aligned MWNTs [5.33]. One of the most promising methods was reported by Ren et al. [5.34], where aligned carbon nanotubes were grown over areas up to square centimeters on nickel-coated glass below 700 °C using a special plasma-enhanced hot-filament chemical vapor decomposition. Dai's group [5.35] presented synthesis of massive arrays of length-controlled carbon nanotubes that are self-oriented on patterned porous and plain silicon substrate. The main points in this method are the use of CVD for nanotube production, the catalytic particle size control by special substrate design, and the positioning of the array by patterning. Forró's group [5.36] produced patterned nanotube films using microcontact printing of pure transition-metal (Fe, Ni, Co) catalysts and their mixtures.

5.1.4 Exotic MWCNT Synthesis Methods

Besides the demonstrated methods, there are peculiar procedures applied for synthesis of MWNTs such as growth from Ni phthalocyanine deposited on a quartz plate by vacuum chemical vapor decomposition [5.37], production of carbon tubes on Ni particles using 2-methyl-1,2'-naphthyl ketone [5.38] at temperatures between 600 and 1000 °C, pyrolytic decomposition of propylene using uniform and straight channels of anodic alumina film as a template [5.39], and many others.

Carbon nanotubes are not only damaged in mechanochemical reactions – they can also be formed in such manner. Chen et al. milled 99.8% pure crystalline hexagonal graphite powder in a Fritsch pulverisette “0” vibration mill in 300 kPa Ar atmosphere for 150 h [5.40] at ambient temperature. The end product of the milling was a disordered nanoporous structure which did not

contain any nanotubes. However, by annealing this material in $1\text{ cm}^3/\text{min}$ N_2 flow for 8 h at 1400°C , they were able to prepare multi-walled carbon nanotubes over $1\text{ }\mu\text{m}$ in length [5.41]. They explained this finding by assuming that the milled material provided nanotube nucleation sites for the growth of SWCNTs and then for MWCNTs via fast surface diffusion of carbon material along the external (0 0 2) surfaces [5.42].

Trace amounts of carbon nanotubes were identified by Wilson et al. in the end product of hexagonal graphite rod milled for 80 h in 2 bar Ar atmosphere and annealed for 6 h at 1400°C in $30\text{ cm}^3/\text{min}$ Ar flow [5.43].

Li et al. have converted 400 mesh, 99.9% pure natural graphite powder into carbon nanotubes directly in the mill by grinding the material for 15 h in Ar atmosphere in a GN2 high-energy ball machine [5.44]. They explain their success based on the special physics of their GN2 instrument, which provides both shear stress and normal stress to the milled powders. However, their results should be treated with caution since there is some discrepancy in the paper concerning the diameter of the nanotubes. Both 80–400 nm (which is too large to be accepted as a carbon nanotube) and 10–50 nm (which is acceptable for a CNT) are reported. They do show a high-resolution transmission electron microscopy (HRTEM) image of an apparently tubular object measuring $\approx 8\text{ nm}$ in diameter, but even this does not provide unambiguous proof because of focusing issues. In a follow-up paper [5.45], the same authors managed to prove the successful synthesis of curled graphite layers and ropes, so in principle, unmistakable evidence for CNT formation could appear in the near future.

Highly curved carbon nanostructures (HCCNs) – potential CNT precursors – were prepared by milling homogeneous mixtures of graphite powder and soot in a shaker mill in air atmosphere [5.46]. The HCCNs were 4–10 nm in diameter and 20 nm in length. HCCNs resembling half-nanotubes 3–6 nm in diameter could also be produced by ball milling highly ordered pyrolytic graphene using tungsten carbide (WC) milling medium [5.47].

MWCNTs can be synthesized by vapor-phase growth methods characterized by the lack of substrate in the pyrolysis chamber. Metallocenes serve as the catalyst precursor, while aliphatic or aromatic hydrocarbons or metallocenes provide the necessary carbon material [5.48]. Product quality is determined by the pyrolysis temperature, gas flow rates, and concentration ratios [5.49]. The main advantage of metallocene-based pyrolytic methods is that they are relatively easy to scale

up; the main disadvantage is the high metallocene cost and the inevitable inclusion of metallic nanoparticles in the produced nanotubes [5.50].

5.1.5 MWCNT Formation Mechanism – Current Understanding

We refer to a recent review by *Nessim* for a detailed account of MWCNT growth mechanism theories [5.51]. It is sufficient to say here that, at the beginning, three basic mechanisms were proposed for the growth of multishell nanotubes: shell-by-shell growth [5.24, 52], curling of graphite sheets [5.53], and simultaneous growth of all shells [5.54].

In the shell-by-shell model, each concentric shell results from carbon adsorption onto the surface of the preceding outer shell. Nevertheless, as discussed in several papers [5.55], carbon atoms and microclusters can be adsorbed onto the surface of nanoparticles only at temperature less than 200 K. This temperature is not sufficient to cleave and reform the bonds between the carbon atoms and hence to form a newer graphitic shell on the external surface. As a result, the growth mechanism for a carbon nanoparticle based on physical adsorption of carbon species onto a graphitic surface is impossible. Since shell-by-shell growth of carbon nanotubes is analogous to the case of nanoparticles, this mechanism is somewhat doubtful.

Another possibility for the shell-by-shell mechanism is that each shell starts growing from the nanotube base attached to the substrate [5.56]. Assuming this possibility, the outer shell could stop growing before reaching the nanotube tip. However, HRTEM results showed that the outer wall of the nanotubes is closed in almost every case.

Another proposed mechanism was the rolling up of large graphite sheets along the lines of sp^3 defects forming nanotubes. However, such a graphite sheet is a parallelogram [5.57] in shape with an acute angle of 30° . It is almost impossible to roll up this sheet into a nanotube with equal number of shells along the length of the nanotube. Scanning tunneling microscopy did not reveal the sheet edges [5.58], which should be found on the surface with the roll structure. Moreover, different walls of MWNTs were found to have different helicity, proving that the nanotubes cannot be formed from a single graphite sheet.

Finally, the third model, i.e., simultaneous growth of all walls, remained as the only possibility for the formation of MWNTs. However, it has to be taken into consideration that up to now there is no proper

Table 5.1 Nonexclusive list of currently operating MWCNT production capacities in the world. Capacity data were obtained from the open literature or from personal communication with the manufacturer

Company	Plant location	Capacity (t/year)
Bayer MaterialScience	Leverkusen, Germany	200

explanation of the step-by-step growth mechanism of multi-walled nanotube formation.

It is postulated that the formation and growth of nanotubes are an extension of other known processes in which graphitic structures are formed over metal surfaces at temperature below 1000 °C from carbon. It is also very obvious that the shape of the graphitic carbon produced depends on the chemical properties and the physical dimensions of the metal particles. The most efficient metals were found to be Fe, Co, and Ni. The peculiar ability of the mentioned metals to form graphitic carbon layers is thought to be related to a combination of different factors. These include their catalytic activity towards the decomposition of carbon compounds, the possibility to form unstable carbides, and finally the speed of carbon diffusion in the metal particle, which must be extremely rapid. *Derbyshire* et al. showed that, over thin metal foils, carbon dissolves to form a solid solution [5.59]. After cooling, the carbon precipitates onto the surface, forming a continuous thin film of highly crystalline graphite parallel to the metal surface. The high crystallinity obtained in a very short time shows that carbon atoms are extremely mobile and able to move easily over and through the metal.

When the size of the metal is in the range of microns, instead of graphite the carbon is produced as filaments of similar diameter. *Baker and Harris* [5.60] proposed a general scheme for the formation of such thin graphitic carbon structures on metal surfaces. In this proposal, the metal particles are supported on a substrate and either strong or weak metal-support interaction is assumed. In the first case, the carbon fiber

grows upwards from the metal particles, which remain attached to the substrate. This is the so-called *extrusion* mechanism. In the case of weak metal-support interaction, the particle is detached from the substrate and moves to the head of the fiber, labeled the *tip-growth* mechanism.

A detailed investigation has been reported on the influence of support and metals on the quality and quantity of carbon nanotubes produced by catalytic decomposition of acetylene. The authors attributed an exceptionally important role to the size and nature of the metal particles and additionally to the alloy phase generation during the reaction. In opposition to the case of single metal particles, the carbon dissolves easily in this alloy phase, which results in an increase of one order of magnitude in the nanotube yield.

5.1.6 Industrial Production

Multi-walled carbon nanotube production is neither difficult nor particularly costly with today's continuous CCVD processes, provided that the multivariate laboratory processes are scaled up adequately [5.61]. Therefore, it seems very likely that the third decade of multi-walled carbon nanotubes will be about commercial products. Global demand for nanotubes was expected to expand rapidly from a small base to more than US \$200 million in 2009. Current forecasts assign a 25% annual growth rate to CNTs, with the market expected to be worth US \$2 billion within 10 years.

Known major MWCNT synthesis capacities worldwide are summarized in Table 5.1. These plants all

use modified proprietary CCVD processes, but differ considerably in their chemical engineering solutions and also in the characteristics of their final product. Although reproducible product quality can be expected from each individual manufacturer, the lack of MWCNT quality standards still makes it difficult to develop any supplier-independent carbon nanotube applications.

Summarizing, global MWCNT production capacity is now over 1700 metric t/year. Comparing this with the annual production capacity of, e.g., platinum (130 metric t/year), cocaine (865 metric t/year) or gold (2300 metric t/year) makes it evident that multi-walled carbon nanotubes have certainly made it up the innovation chain from laboratory curiosity to a commercial product of their own. It is even more interesting to realize that the global polyacrylonitrile (PAN)-based carbon nanofiber production capacity was only one order of magnitude larger (25 000 metric t/year) in 2006.

5.1.7 Quality Assessment

Contemporary synthesis methods are unable to yield pure multi-walled carbon nanotubes in macroscopic amounts in the chemical sense of the word *pure*, meaning that any random sample taken from the material should have exactly the same composition, exhibit the same features, and contain the same molecules/crystals as any other sample. The major reasons behind the chemical heterogeneity of MWCNTs are:

- Differences due to the unequal chirality of the MWCNT walls
- Differences due to the varying length, diameter, and number of walls between tubes
- Differences between the crystallinity of the walls, number of defects, presence of open tube ends, and radial micro/mesopores
- Functionalization of the nanotube surface and/or inner channel
- Presence of carbonaceous contaminants (e.g., condensed polyaromatic hydrocarbons) on the walls

- Presence of amorphous carbon particles separated from the nanotubes
- Presence of catalyst support particles
- Metallic impurities (catalyst particles) either embedded into the MWCNT or deposited on the nanotube wall or deposited on the catalyst support particles
- Technological contamination resulting from, e.g., washing or functionalization steps.

The most important characterization method of MWCNTs is transmission electron microscopy (TEM). TEM sample preparation methods were reviewed by Caplovicova et al. [5.62], whereas TEM analysis is discussed by many authors [5.63–65]. Care must be exercised to avoid misinterpreting TEM images because of artifacts originating from the carbon films used on TEM grids [5.66]. Very nice science can be done when MWCNT modification studies are undertaken in situ in a TEM instrument [5.67–71]. Low-magnification ($\times 10$ –60k) TEM images can be used to measure nanotube length distributions and to assess the ratio of non-nanotube impurities by counting nanotubes and irregular objects (e.g., amorphous carbon or catalyst support) per unit area. Normal TEM and scanning electron microscopy (SEM) can also be used for determining tube outer diameter distributions [5.72–74]. The number of walls, the diameter of the inner channel, and the crystallinity of the walls are measured in high-resolution TEM (HRTEM) images [5.75]. The presence of noncarbonaceous impurities can be quantified by classical analytical methods, x-ray fluorescence [5.76], energy-dispersive x-ray spectroscopy combined with TEM or SEM [5.77], magnetic methods [5.78] or neutron activation analysis [5.79]. The amount of amorphous carbon debris is derived from Raman spectroscopy [5.80] or thermogravimetry [5.81, 82]. The amount of condensed aromatic contaminants stacking to the walls can be quantified by extracting these impurities from the nanotubes and performing comparative spectroscopic measurements on the solution or on the nanotubes themselves [5.83, 84].

5.2 Chemistry of MWCNTs

The chemistry of multi-walled carbon nanotubes focuses on the purification and functionalization of the material. Concepts from fullerene, SWCNT,

and graphite chemistry are generally applicable to MWCNTs as well, provided that MWCNT-specific characteristics are taken into account.

5.2.1 Purification of Raw MWCNTs Obtained by Various Methods

The purification of MWCNTs has been developed in parallel with the synthesis methods [5.85]. Some recent reviews on this topic are available from Hou et al. [5.86] and Matlhoko et al. [5.87]. Summarizing, liquid-phase oxidation followed by acid leaching appears to be a good overall solution for most CVD-grown nanotubes. Alviño-Paez et al. suggested an efficient soft purification procedure that is recommended for applications where keeping the nanotube structure intact is mandatory [5.88].

Removal of Catalysts and Catalyst Supports

For production of MWCNTs by catalytic decomposition of hydrocarbons, supported metal catalysts are generally used. The most frequently applied metals are Co, Fe, and Ni or their mixtures [5.89, 90]. Supported metal catalysts are prepared by impregnating the surface of an oxide-like support (such as silica, alumina or zeolites) with a solution of the given metal salts. Zeolite and silica supports can be separated from the carbon product by leaching the primary product in hydrofluoric acid (38–40%) for 48 h under vigorous stirring followed by filtration and washing [5.27, 91]. The resulting wet cake contains various forms of carbons as discussed above. When alumina is the support, its extraction differs from those previously described. A sodium hydroxide solution is used instead of HF solution, since alumina can be easily dissolved in concentrated hydroxide solution. The most economical method is growth of MWCNTs on a water-soluble support, e.g., the *wash and go* method where transition metals supported on NaCl are used as CCVD catalysts [5.92].

Upon treatment of the catalyst–carbon mixture, the metal component of the catalysts is generally also transferred into the solution. If not, further treatment in diluted mineral acid solution is recommended [5.93]. It should be mentioned that metal particles encapsulated into the carbon nanotubes remain intact after this treatment. For their removal, we should first open the nanotubes, which are generally produced with closed ends. MWCNTs can be uncapped by oxidation [5.94] and by treatment in a molten LiCl–KCl eutectic [5.95].

Removal of Amorphous Carbon

There are chemical and physical methods to purify samples of carbon nanotubes containing by-product car-

bon material. The chemical methods generally result in products of higher purity but often modify the starting material irreversibly.

In order to remove amorphous carbon, the catalyst-free material can be either oxidized or reduced [5.96]. Reduction is generally performed in hydrogen atmosphere at elevated temperature (above 800 °C). Oxidation of carbon forming irregular structures can be performed either in gas or in liquid phase. Gas-phase oxidation occurs at 500 °C in air. In 210 min, such treatment results in carbon nanotubes of purity higher than 95%. Instead of air, oxygen or ozone can also be used. When purification is carried out in solution, use of an acidic (0.5 M sulfuric acid) KMnO₄ solution (0.3 M) is recommended. After 1 h of reaction at 80 °C, carbon nanotubes of 95% purity are obtained. Other liquid-phase oxidation processes rely on conc. HNO₃ treatment [5.83], H₂SO₄/HNO₃, NH₄S₂O₈, H₂O₂, ozone, and chlorine water [5.97, 98]. Oxidative digestion procedures can be intensified by microwave treatment [5.99–101] or ultrasound. Ultrasound at 300 kHz generates less structural damage in MWCNTs than the common 20–35 kHz range [5.102]. Wang et al. reported on the simultaneous cutting and oxidative purification of MWCNTs in molten KNO₃ (MWCNT : KNO₃ = 1 : 40 by mass, 340–420 °C, 12 h) [5.103]. It is important to realize that oxidative purification procedures generate functionalized carbonaceous debris which should be removed by aqueous bases before subsequent processing steps [5.84]. Alternatively, debris gasification in CO₂ atmosphere at 525 °C can also be applied [5.104].

Methods that deliberately functionalize the nanotubes are also utilized. Bromination [5.105, 106], 1,3-dipolar cycloaddition of azomethine ylides [5.107], and even HNO₃ oxidation [5.108, 109] can be considered. Functionalization renders the MWCNTs soluble and thus facilitates their separation from contaminants. Reduction or high-temperature annealing should be used after purification to get the original MWCNT structure back.

MWCNTs can be purified in situ by a post plasma-enhanced CVD (PECVD) hydrogen plasma treatment, which removes both metallic impurities and residual carbonaceous particles [5.110]. Precisely controlled oxidation in air can burn out amorphous carbon without damaging the nanotubes [5.111]; For example, a 450 °C, 180 s treatment can be applied to purify vertically aligned MWCNT forests [5.112].

In some instances these treatments lead to uncapping of nanotubes, which are therefore ready to be filled

with gases or metals. Some chemical functionalization, such as implantation by hydroxyl, carboxyl, etc. groups, can also take place.

Centrifugal separation is generally applied for further purification of nanotubes. First, a dilute aqueous NT solution is prepared and an appropriate amount (0.1%) of an ionic surfactant such as benzalkonium chloride is sonicated in an ultrasonic bath for 4–6 h. Then, the colloidal suspension is centrifuged, first at 2000 g in order to separate large carbon particles ($d = 50\text{--}80\text{ nm}$) followed by a second step at 20 000 g in order to precipitate nanospheres with $d < 50\text{ nm}$. The result is a product with NTs of 70% purity.

Microfiltration separation is appropriate for soots containing a higher yield of NT, since the nanoparticles easily contaminate the membrane filter. Therefore, centrifugal purification is usually applied before microfiltration. First the soot is soaked in CS_2 to remove fullerenes and other soluble materials from the sample. The next step is to disperse the material in water containing 0.1% surfactant, followed by agitation in an ultrasonic bath. The suspension is then filtered on a $0.2\text{ }\mu\text{m}$ -pore-size membrane filter. The NTs are caught by the filter.

Ultimately, MWCNTs can be purified by size exclusion chromatography (SEC) as well [5.113]. In addition to the removal of catalysts and amorphous carbon, length separation can also be achieved [5.114]. Electrophoretic methods have recently been introduced to separate different MWCNTs from each other [5.115].

Opening Up of Carbon Nanotubes

The simplest method to open nanotubes is their oxidative treatment. It is well known that graphite oxidizes primarily at defects of the hexagonal lattice to create etch pits. When such defect sites are present in the wall of the nanotubes, they become the center of preferential etching. However, nanotubes have additional structural features such as high curvature and helicity, and may contain five- and seven-membered rings, which modify the initiation and also the propagation of oxidation. Particularly for MWNTs, the oxidation tends to start near the tips, providing a mechanism for opening the tubes. Oxidation proceeds layer by layer, resulting in thinner tubes. Once the tip is removed, the strain induced by the distribution of pentagons is no longer there. The concentric layers of MWNTs do not react at the same rate, since each shell has its own tip. It follows that the inner shells might persist longer than the outer ones. There-

fore, different oxidation rates are assumed for oxidation of an open MWNT.

Upon treatment, carbon nanotubes are refluxed in concentrated HNO_3 , H_2SO_4 or KMnO_4 solution, or at room temperature in superacidic HF/BF_3 solution, or even in aqueous solution of OsO_4 or $\text{OsO}_4\text{--NaIO}_4$ for 24 h until their originally capped ends open up [5.116]. Treatment in acidified KMnO_4 solution seems to be a somewhat better procedure. The advantage of HF/BF_3 treatment is that it is carried out at room temperature. As mentioned before, oxidative treatment of nanotubes results not only in nanotubes open at their tips, but also nanotubes that are thinner in diameter [5.117]. The extent of the thinning depends on the duration of treatment. A further consequence of oxidative treatment is partial functionalization of the tubes; i.e., the nanotubes become covered with carboxyl or hydroxyl groups at their ends. These functional groups make the NTs partially soluble. The number or concentration of the inserted carboxyl groups can be estimated by simple acid–base titration. The concentration of the surface acid groups on nanotubes opened by various oxidants is in the range of 2×10^{20} – 10×10^{20} sites per gram of nanotube [5.118].

Improving Graphitization

Annealing MWCNTs at very high temperatures (up to 3000°C) in an inert atmosphere improves their quality [5.119] by favoring the formation of graphitic structures over those of less stable carbon species, including sp^3 defect sites [5.120]. This has been explicitly demonstrated by Kanyo et al., who measured ethanol adsorption excess isotherms on CCVD-synthesized MWCNT surfaces annealed between $1000\text{--}1400^\circ\text{C}$ and demonstrated the conversion of the mostly hydrophilic, functionalized starting material into a hydrophobic, graphitic nanotube structure at high temperature [5.121]. Annealing at 1000°C in NH_3 atmosphere improved the hydrogen storage capacity of MWCNTs from 0.39 wt% to 2.9 wt% at 6.89 MPa [5.122].

5.2.2 MWCNT Functionalization

Multi-walled and single-walled carbon nanotubes exhibit some very similar chemical properties; therefore, approaches discussed for SWCNTs can also be attempted for MWCNT functionalization. The most important difference is that, due to their larger outer diameter and consequently lower curvature, MWCNTs are less reactive than their single-walled counterparts.

The chemical properties of carbon nanotubes are governed by three factors:

1. The sp^2 hybridization of the carbon atoms arranged into hexagonal rings to form the nanotube walls and the distortion of these hybrid orbitals due to curvature-induced strain (quantitatively characterized by the pyramidalization angle) [5.123, 124]
2. The π orbital misalignment between adjacent carbon atom pairs [5.125, 126]
3. The presence of sp^3 defect sites in the walls.

Both the pyramidalization angle and the π orbital misalignment angle scale inversely with the tube diameter; therefore, there is a direct correlation between nanotube diameter and addition reaction affinity [5.127].

On the other hand, MWCNTs are often found to be readily transformable in chemical reactions. This is due to the fact that most MWCNTs are synthesized by CCVD methods and thus their outer surface features a high sp^3 defect concentration. These defects serve as bridgeheads for further chemical transformations and may facilitate the solubilization of MWCNTs and the preparation of homogeneous MWCNT dispersions in polymer matrices.

Functionalization reviews are available from, e.g., Musso et al. [5.128] and Karousis et al. [5.129]. The chapter by Hauke and Hirsch is particularly comprehensive about the covalent functionalization of carbon nanotubes [5.130].

Noncovalent Functionalization

MWCNTs exhibit high affinity towards long-chain organic molecules to form noncovalent adducts where the nanotube is wrapped into the chains of the partner molecule. Such adducts are relatively easy to prepare from the chemical point of view, but require careful MWCNT disentanglement and product separation techniques to provide meaningful results. Noncovalent functionalization agents tested with MWCNTs include DNA [5.131, 132], proteins [5.133], enzymes [5.134, 135], dendrimers [5.136], β -cyclodextrins [5.137, 138], porphyrins [5.139], dyes [5.140], and various polymers [5.141–152].

Water-soluble porphyrins can be used to form electron donor–acceptor nanohybrids with carbon nanotubes. The stability of radical ion pairs was better for MWCNTs (5.8 μ s) than for corresponding SWCNT-based systems (0.5 μ s) [5.153–155]. The attachment of surfactants is considered as noncovalent functionaliza-

tion and is discussed in Sect. 5.3. Reaction partners for noncovalent MWCNT functionalization are usually prepared before the reaction. However, Tang and Xu reported on the synthesis of water-soluble MWCNT–poly(phenylacetylenes) prepared by in situ polymerization of phenylacetylene [5.156].

Covalent Functionalization

Functionalization methods developed for graphene and single-walled carbon nanotubes can be adapted for forming functional groups on MWCNT walls, which exhibit reactivities falling between these two extremes. It should be noted that MWCNTs are often covered by amorphous carbon and polycondensed aromatic hydrocarbon fragments after synthesis. Since these are more reactive than the nanotubes themselves, failure to remove these contaminants prior to functionalization can easily result in overestimation of the extent of nanotube functionalization.

Although even sonication in water can create oxygen-containing functional groups (hydroxide, carbonyl, carboxyl) on the nanotube surface [5.157], these groups are mostly formed during the oxidative purification of the MWCNTs as discussed in Sect. 5.2.1. This method can be varied extensively, starting from the simplest HNO_3 digestion up to the asymmetric end functionalization of MWCNTs which was achieved by embedding a vertically aligned MWCNT array in a protective polystyrene matrix, oxidizing their tips with water plasma, and floating the assembly on the top of a reactive solution [5.158]. Carboxylated MWCNTs can be converted to open nucleophilic chemistry routes [5.106, 159] or coupled with ionic materials such as 1-hydroxyethyl-3-hexyl imidazolium chloride [5.160, 161] or zwitterion intermediates [5.162].

Direct sidewall addition reactions reported to work on MWCNTs include epoxidation [5.163], [2 + 1] cycloaddition [5.164], Prato reaction [5.136, 165–169], [4 + 2] cycloaddition (also known as Diels–Alder reaction) [5.170–172], and Friedel–Crafts-type acylation [5.173]. Reductive alkylation under Birch conditions is also possible on MWCNTs [5.174].

Radical chemistry can be used to graft polymers onto MWCNTs [5.175]. Benzoyl peroxide is a possible carbon-centered free radical initiator that was shown to activate poly(oxyalkylene)amines [5.176]. Oxygen-centered free radicals are generated from hydrogen peroxide and can introduce OH, COOH, and quinone groups onto the nanotubes [5.177]. MWCNT–liquid crystal nanocomposites were prepared by exploiting electron transfer from lithium naphthalene radical

anion to the MWCNT surface [5.178]. Nitroxide-mediated radical polymerization of 4-vinylpyridine and sodium 4-styrenesulfonate was demonstrated to yield water-soluble, covalently bonded MWCNT–polymer adducts [5.179].

Mechanochemical Functionalization

The simplest mechanochemical CNT functionalization reactions are adduct formations in which nanotubes are mixed with potential modifiers and milled vigorously in a high-energy vibrating mill. Successful nanotube functionalization with DNA [5.180, 181] gave MWCNT–DNA complexes with a remarkable 5 mg/ml water solubility. The literature on covalent mechanochemical functionalization is somewhat underdeveloped, most probably because of the broad variety of wet chemical functionalization techniques available [5.182]. Nevertheless, the improved chemical reactivity [5.183] of strained sites in MWCNTs can be very efficiently utilized in mechanochemical reactions as well.

The general synthesis strategy is to mix CNTs with adequate functional group precursor molecules and then let the high-energy ball impacts initiate reactions between the partners. The technique was developed by Kónya et al., who milled MWCNTs in reactive atmospheres such as CO, Cl₂, NH₃, COCl₂, H₂S, and CH₃SH using a low-impact vibration mill for 100 h [5.184, 185]. The resulting material was covered with simple functional groups which can be used as bridgeheads for subsequent derivatization reactions. Further applications of this concept include the functionalization of SWCNTs with the alkyl halides trifluoromethane, trichloromethane, tetrachloroethylene, and hexafluoroprene [5.186], and the synthesis of water-soluble *nanotubols* by ball-milling SWCNTs with KOH [5.187].

Filling of MWCNTs

Opened MWCNTs can be filled using capillary forces provided that the surface tension of the filling medium is not above 200 mN/m [5.188, 189]. Successful reports on using metals [5.190–192], metal oxides [5.193–197], nitrates [5.198], and chlorides [5.199] are available in

the literature. Some of these species can be reduced within the nanotube by H₂ gas flow into the corresponding metallic nanowires [5.118, 200, 201].

Nanoparticles on MWCNTs

Metallic nanoparticles and semiconducting quantum dots can both be mounted successfully on MWCNTs. To decorate MWCNTs with gold nanoparticles, carboxyl groups are first formed by oxidation. Treatment with NaOH converts these into carboxylate ions that can be alkylated with 2-bromoethanethiol to yield MWCNT–SH derivatives. Both premade and in situ-synthesized gold nanoparticles can react readily with these derivatives [5.202–204].

To anchor quantum dots to MWCNTs, Pan et al. first created carboxylic acid functionalities on MWCNTs and then converted the surface to an amine-decorated one by reacting the carboxyl groups with ethylenediamine [5.205]. CdSe quantum dots functionalized by mercaptoacetic acid were then reacted with the amine groups and thus anchored onto the MWCNT surface. CdTe quantum dots could also be attached to the nanotube by the same method using *para*-phenylenediamine as a linker molecule [5.206]. The direct link between the quantum dot and the nanotube quenches the CdTe photoluminescence. However, by using a poly(2-dimethylaminoethyl)methacrylate coating and subsequent quantum dot anchoring, the luminescent properties can be retained. The same strategy could also be applied for synthesis of MWCNTs decorated with magnetic Fe₃O₄ nanoparticles [5.207].

Covering MWCNTs with inorganic nanoparticles is an emerging field with huge application potential in photocatalysis and sensorics. Nanocomposites of multi-walled carbon nanotubes with hydroxyapatite [5.208], TiO₂ [5.209–211], rare-earth fluorides [5.212], SnO₂ [5.213–215], ZnO [5.216], V₂O₅ [5.217], Bi₂O₃ [5.218], WO₃ [5.219], and WS₂ [5.220] are typical examples of this material type. Although sol-gel methods make it very easy to synthesize such MWCNT–oxide mixtures, ensuring that the inorganic particles are indeed decorating the nanotubes instead of forming a separate phase is very difficult.

5.3 Properties

As-synthesized multi-walled carbon nanotubes appear as fluffy black powder with a very low apparent density between 0.03 g/cm³ and 0.22 g/cm³. The skeletal density of MWCNTs was measured to be 1.74 g/cm³

in 2009 [5.221]. Today, skeletal densities of 2.1 g/cm³ are usually reported. MWCNTs are agglomerated after synthesis and can be separated by physical methods [5.222]. Purification and functionalization in solu-

tion result in an agglomerated, dense material which is difficult to disperse again even by using high-energy ultrasonic horns. The solubility of MWCNTs is very low in all liquids, and the stacking of MWCNTs caused by the high (500 eV/μm) tube–tube van der Waals interaction energy [5.223] makes creating stable solutions a very challenging task. Actually, the term *solution* should not be used for MWCNTs at all. Rather, multi-walled carbon nanotubes form colloidal solid/liquid (S/L) dispersions in solvents, and therefore MWCNT solutions should be referred to as sols [5.224].

The stability of MWCNT dispersions in water can be increased by several methods including (i) shortening of the nanotubes [5.225], (ii) surface functionalization (e.g., 1.2 mg/ml MWCNT in water [5.162]), and (iii) use of surfactant molecules. Stable dispersions of untreated multi-walled carbon nanotubes feature concentrations below 0.05 mg/ml in water, whereas carboxy-functionalized MWCNTs can be dissolved up to 0.5 mg/ml. The redox pair ammonium persulfate/diethanolamine can be used to prepare MWCNT dispersions stable in water up to 4 days [5.226]. The choice of the functional group largely affects the solubility. Shen et al. reported that amino-functionalized MWCNTs get cross-linked through diamine connecting units to form large, insoluble aggregates, whereas carboxylic acid functionalities improve dispersibility in water [5.227]. Ester derivatives of MWCNTs are soluble in chloroform, and their solubility depends on the chain length of the attached aliphatic groups [5.228]. Surfactant molecules frequently used for improving carbon nanotube dispersibility are sodium dodecyl sulfate (SDS) [5.229, 230], sodium dodecylbenzene sulfate (SDBS) [5.231], octyl phenol ethoxylate (Triton X-100) [5.232], hexadecyltrimethylammonium bromide (CTAB) [5.233], poly(diallyldimethylammonium) chloride [5.157], and poly(methyl methacrylate) derivatives [5.234]. Inorganic compatibilization agents are also used. Loginov et al. reported MWCNT concentrations up to 0.5 wt% in water when using laponite [5.235]. Very high nanotube concentrations (up to 10 mg/ml) can be reached by simultaneously functionalizing the nanotube surface (e.g., acyl chloride activation) and applying a surfactant and/or wrapping agent such as a small peptide or even the simple amino acid lysine [5.236]. Madni et al. utilized reversible noncovalent functionalization to achieve 1 wt% MWCNT (approximately 1 mg/ml) by using a 1:1 mixture of a cationic (dodecyltrimethylammonium bromide, DTAB) and an anionic (sodium octanoate, SOCT) surfactant [5.237]. Even higher concentrations (7.4 mg/ml and 29.2 mg/ml, respectively)

were reported for irreversible noncovalent functionalization of MWCNTs by using hydrolyzed poly(styrene-co-maleic anhydride) carrying pyrene (HPSMAP) [5.238] or hydrolyzed poly(styrene-co-maleic) anhydride (HSMA) [5.239]. Nonaqueous solvents are also used for carbon nanotube dispersion [5.224]. Since surfactants are not always utilized in this case, the properties of the solvent are critical. Slightly polar organic solvents with surface tension close to 40 mJ/m² are known to work well. Surfactants specifically designed to facilitate dispersion of MWCNTs in nonpolar sol-solvents used in sol–gel synthesis have appeared recently in the literature; For example, the surfactant dabcosil stearate contains a stearate-based 18-carbon alkyl chain as an anion and a silsesquioxane containing a bridged, positively charged 1,4-diazoniabicyclo[2.2.2]octane group [5.240].

The specific surface area (A_S) of MWCNTs with both ends opened is determined by the number of walls N roughly as $A_S = 2360/N$ [m²/g]. The cavity of open MWCNTs is available for adsorption governed by capillary condensation (unlike in SWCNTs, where micropore filling is dominant) [5.241]. MWCNTs with one open end have a hysteresis-free adsorption–desorption profile, in agreement with theoretical predictions [5.242]. Although this makes nanotubes good candidates for nanoscale gas cylinders, reactors [5.243] or templates [5.244–246] for other one-dimensional nanomaterials, the majority of MWCNT samples are capped at both ends. The measured specific surface area of closed MWCNTs is 190–350 m²/g, depending on the number of walls, the purity of the sample, and the ratio of opened to closed nanotubes. Peigney et al. published correlation charts useful for theoretical prediction of MWCNT specific surface area [5.247]. The pore system of capped MWCNTs is characterized by adsorption in 20–40 nm aggregated pores, which are actually intertube openings between relatively loosely attached nanotubes [5.248]. In practical applications, MWCNTs behave as mesoporous materials with mesopore volume of 0.5–2.0 cm³/g.

The x-ray diffraction profile of MWCNTs is dominated by the (002) peak (indexed on the basis of the hexagonal close-packed graphite unit cell) which probes the interwall spacing. This peak is found at $2\theta = 26^\circ$ when measured with Cu K_α radiation and is broadened because of the finite number of walls and their curvature. The (100), (004), and (110) peaks are usually noticeable at 44° , 53° , and 78° , respectively [5.249]. X-ray diffraction (XRD) is not considered to be a major characterization technique for MWCNTs, mostly because the measured profiles

are often complicated by the signal of leftover catalyst impurities. However, the ability of XRD to measure the interlayer spacing rendered it very important for all interwall filling studies [5.250, 251], most importantly Li^+ intercalation [5.252] and H_2 storage [5.253] measurements. Moreover, advanced x-ray diffraction methods can provide information about the crystal structure of aligned MWCNT forests [5.254].

5.3.1 Mechanical Properties

In principle, the mechanical properties of MWCNTs in the axial direction are exceptional, with Young's modulus in the TPa range [5.255] and tensile strength of 60 GPa [5.256]. MWCNTs are softer in the radial direction, as indicated by a radial Young's modulus of 30 GPa [5.257] and up to 40% radial deformability [5.258]. On the basis of direct TEM observation, Demczyk et al. calculated the Young's modulus and tensile strength to be 0.8 TPa and 0.15 TPa, respectively [5.68]. It is important to note that (i) the cross-sectional area of MWCNT is not reduced before mechanical failure, and (ii) the outermost shell is the only load-bearing element, because of the ultralow friction between the MWCNT walls [5.259]. The friction during the cyclic telescopic motion of MWCNTs was found to be less than 1.4×10^{-15} N/atom by Kis et al. [5.260]. Defects decrease the strength of the individual shells but improve the load transfer between walls [5.261], therefore exhibiting a complex overall effect on the mechanical properties of MWCNTs. The locally probed Young's modulus of coiled MWCNTs is comparable to that of straight nanotubes [5.262].

The spring constant of MWCNT cantilevers can be as small as 0.001 N/m and was found to be tunable by adjusting the length of the nanotube [5.263]. Carbon nanocoils can be elongated to 42% of their original length and behave like an elastic spring with spring constant of 0.12 N/m in the low-strain region [5.264]. The fundamental resonance frequency of coiled MWCNTs ranges from 100 to 400 MHz, which can be exploited in creating resonators sensitive to mass changes in the sub-attogram range [5.265].

The low radial strength of MWCNTs makes it relatively easy to modify them by mechanical forces. The most evident macroscopic effect of ball milling is the fast increase of the apparent sample density. In a low-energy vibrational mill, the originally fluffy and thin ($\rho_{\text{appar}} = 0.07 \text{ g/cm}^3$) starting MWCNT material was transformed into a dense black powder ($\rho_{\text{appar}} = 0.38 \text{ g/cm}^3$) after ≈ 1 h of milling and kept

this form until the end of the experiment [5.266]. It is generally agreed that this thickening is due to the loss of air trapped within the intertube spaces of the nanotube aggregates. Disentanglement of CNTs by ball milling is an alternative to ultrasonication and chemical treatment [5.267–269]. Wang et al. compared several disentanglement methods including ball milling and found that only chemical treatment can give truly separated, individual nanotubes [5.222]. Willemis and coworkers have also confirmed that MWCNTs synthesized on MgO-supported transition-metal catalysts by chemical vapor deposition cannot be separated by ball milling [5.270]. They observed that oxidative treatment before the milling makes the nanotubes more liable to mechanical cutting and subsequent separation, and explained this finding based on the weakening of the nanotube wall structure at sites where oxygen-containing functional groups were formed.

The end morphology of milled carbon nanotubes is an important topic of its own. All reports agree that nanotubes with open tips appear during milling. However, a more detailed investigation by Konya's group revealed that a considerable amount of tube ends have partially or completely collapsed openings [5.271]. Kinks are known to develop in carbon nanotubes during bending, with strain energy concentrated in the kink area [5.272, 273]. The concentration of strain energy in the kink area weakens the material strength of the nanotube and therefore is the preferred site to break.

5.3.2 Electromagnetic Properties

The electronic properties of individual MWCNTs have not yet been studied as extensively as those of single-walled nanotubes [5.274–277]. The longitudinal polarizability of MWCNTs is given by the sum of the polarizabilities of the constituent tubes. The transverse response is dominated by the outer layers [5.278]. It is generally accepted that the helicity of the outermost wall determines the properties of the MWCNTs at low bias and temperature [5.279–281]. This is why Collins et al. have succeeded in burning the outermost metallic walls of MWCNTs by passing a large current through the tube and ending up with semiconductor-only nanotubes [5.282, 283]. The interesting feature here is that the inner walls of MWCNTs do not necessarily feature the same helicity, and shell-to-shell interactions are nonnegligible. In fact, such interactions are thought to be responsible for the significantly lower resistance of MWCNTs with a large number of walls [5.284, 285]. The electrical current

conductivity of arc-discharge-synthesized MWCNTs is 10^4 S/m [5.12] and that of annealed CVD MWCNTs is 2×10^5 S/cm [5.286], which renders them useful for lightweight wire and cable applications (compare with 59.6×10^6 S/m for pure copper). Electrical conductivity in the longitudinal direction is an order of magnitude higher than in the transverse direction [5.287].

MWCNTs can support extremely high current densities and tolerate very high temperatures. The early measurements of Kaneto et al. indicated that more than 10^6 A/cm² can flow through an individual nanotube [5.288]. Plasma-enhanced CVD-derived MWCNTs have pushed this limit up to 10^8 A/cm² [5.289], and Zettl's group verified that MWCNTs can maintain up to 2×10^8 A/cm² even at 3200 K [5.290].

The magnetic moment of MWCNTs is a controversial topic because of the lack of standardized, metal-catalyst-free nanotube samples [5.291]. On the other hand, the magnetic properties of the embedded transition-metal particles can be studied well [5.292]. Wang et al. recently reported on giant magnetic moment enhancement of nickel nanoparticles in MWCNTs [5.293]. The magnetoresistance [5.294, 295] of MWCNTs is negative and can be described adequately by conventional weak localization theory [5.280]. Electronic states near the energy gap have an orbital magnetic moment larger than the Bohr magneton [5.296].

The ¹³C nuclear magnetic resonance (NMR) signal of MWCNTs broadens roughly proportionally with the number of walls [5.297], which makes direct NMR observations on multi-walled carbon nanotubes difficult. On the other hand, NMR has been successfully utilized for monitoring H₂ [5.298] and Xe [5.299, 300] adsorption on MWCNTs and also for verifying functionalization reactions performed with simple functional groups such as -NH₂ [5.301] as well as with organic partners, e.g., octadecylamine [5.302], polyisoprene [5.303], poly(ϵ -caprolactone) [5.304], and [4 + 2] Diels–Alder cycloaddition reagents [5.305].

The electron paramagnetic resonance (EPR or ESR) spectrum of MWCNTs is characteristically different from that of SWCNTs because the latter exhibit a double peak linked to spin-charged separation, whereas MWCNTs have a single narrow asymmetric peak [5.306] with splitting factor of $g = 2.2529$ and peak-to-peak (pp) line width of $\Delta H(\text{pp}) = 890$ G [5.307]. Actual MWCNT electron spin resonance (ESR) measurements have exhibited considerable variation in their results depending on the extent of metallic impurity removal, size distribution, and doping effects [5.308–310]. Neverthe-

less, ESR has been successfully used to study MWCNT synthesis [5.311], purification [5.312], and modification [5.313]. Both the g -value and the ESR line width increased after thermal annealing [5.314, 315].

5.3.3 Thermal Properties

We refer to the work of Dresselhaus and Eklund for a treatise on phonons in carbon nanotubes [5.316]. The thermal conductivity of aligned MWCNT films was found to be 15–25 W/(m K) when measured with the 3ω technique [5.317, 318]. By taking the volume filling fraction into account, this number translates to an effective average thermal conductivity of 200 W/(m K) for MWCNTs [5.287]. Recently Gaillard et al. reported on measuring thermal conductivities between 180 and 220 W/(m K) for MWCNT carpets by using time-resolved laser pyrometry [5.319]. Measurements performed on individual multi-walled carbon nanotubes yielded thermal conductivities around 650–830 W/(m K) for supported [5.320] and over 3000 W/(m K) for free-standing suspended [5.321] MWCNTs at room temperature, respectively. These findings were confirmed by theoretical calculations [5.322] and independent experiments [5.323]. Chiu et al. found phonon transport in MWCNTs to be ballistic and were able to determine the thermal conductance quantum (6×10^{-6} W/K) and the phonon mean free path (220 nm) as well [5.324]. Yan et al. reported that strong intertube coupling in MWCNTs could be responsible for low thermal conductivity [5.325]. The specific heat of MWCNTs was analyzed by several authors and found to be similar to that of graphite but influenced heavily by the arrangement of the nanotubes (e.g., aligned nanotubes, ropes, etc.) [5.326]. A 0.6 vol% suspension of MWCNTs in water was found to increase the thermal conductivity of water by up to 38% [5.327, 328]. In a study comparing the thermal conductivity enhancement of several nanofluids, Hwang et al. reported on an increase of up to 11.3% at a volume fraction of 0.01 [5.329].

5.3.4 Spectroscopic Properties

Raman spectroscopy has rapidly become a pivotal technique for studying carbon nanotubes [5.330–338], especially for SWCNTs. The Raman spectrum of MWCNTs is dominated by two peaks: the G band (E_{2g}) at 1590 cm^{-1} , which corresponds to tangential stretching C–C vibrations in the nanotube wall plane (in graphite a single peak at 1582 cm^{-1} is found), and

the D band at 1350 cm^{-1} , which originates from a double resonance process [5.339, 340] and is attributed to the presence of amorphous disordered carbon. It should be emphasized that the D band is not a good measure of nanotube wall defects; rather, its intensity is proportional to the amount of amorphous carbon in the system [5.341, 342]. Nevertheless, measuring the intensity ratio of the D and G bands is a widely accepted method of assessing the general purity of a multi-walled carbon nanotube sample [5.343]. The radial breathing mode, a distinctive feature of single-walled carbon nanotubes, is visible in double-walled carbon nanotubes but is usually not observed in MWCNTs [5.344, 345]. Micro-Raman measurements on highly crystalline hydrogen direct-current (DC) arc discharge multi-walled carbon nanotubes indicated the existence of another peak characteristic of MWCNTs at 1840 cm^{-1} [5.346], which was tentatively attributed to the presence of short carbon chains within the nanotubes [5.347, 348] or interconnecting nanotube surfaces [5.349]. The G' peak originates from two-phonon scattering phenomena around the K point (feature at approximately 2700 cm^{-1}) and around the M point (approximately 2730 cm^{-1}) in the Brillouin zone [5.350]. Several additional peaks of very low intensity can be identified in high-quality MWCNT Raman spectra below 500 cm^{-1} . These were associated with the radial breathing modes of the thinnest inner walls.

The optical spectrum of MWCNTs from the ultraviolet (UV) to the infrared range is different from SWCNTs insofar as it does not depend on the chirality of the outermost shell, but rather, the reflectivity is determined by the topology of the bulk nanotube phase and the polarization orientation with respect to the applied field [5.351]. A model for the dielectric function developed from Maxwell's equations is available from Garcia-Vidal et al. [5.352]. Kamarás et al. provide comprehensive broadband optical characterization of various carbons including MWCNTs [5.353]. A π plasmon near 5 eV determines the optical absorption of MWCNTs. MWCNTs exhibit optical limiting properties in the visible and infrared range. Sun et al. reported limiting thresholds of 1, 5, and 13 J/cm^2 at 532, 700, and 1064 nm, respectively [5.354]. An interesting consequence of the MWCNT optical properties is the existence of the world's darkest material, a low-density aligned MWCNT array synthesized by Ajayan's group which has an integrated total reflectance of 0.45% [5.355]. Photoluminescence from MWCNTs was reported by Brennan et al. even though theoretical expectations favored nonradiative decay because

of intershell coupling effects [5.356, 357]. Although later studies confirmed the possibility of photoluminescence (PL) from isolated [5.358] or thiol-functionalized standalone MWCNTs [5.359], it is far more common to dope multi-walled carbon nanotubes with quantum dots [5.360, 361] or metal complexes [5.362–364] to achieve photoluminescence. It should also be noted here that MWCNTs were shown to quench the PL effect of certain quantum dot [5.365] and polymer [5.366] composites; therefore, care must always be exercised when evaluating MWCNT photoluminescence measurements.

The infrared spectrum of MWCNTs can be measured in transmission by, e.g., mixing the nanotubes into KBr pellets or in reflection-absorption geometry using a gold mirror as sample holder. Some claimed MWCNT-specific infrared (IR) spectral features include the 1445 cm^{-1} peak [5.367], the G band (1584 cm^{-1}), and the D band (1200 cm^{-1}) [5.368]. Additional peaks associated with O–H vibrations (1600 and 3450 cm^{-1}), carboxylic groups (1725 cm^{-1}), and C–H stretching vibrations (close to 3000 cm^{-1}) are also frequently observable in the spectra, even though they correspond to defects and impurities rather than the MWCNT structure itself. The most important use of infrared spectroscopy in MWCNT research is the characterization of surface functionalization [5.369–372].

Photoelectron spectroscopy of MWCNTs revealed that their work function (4.3 eV) is lower than that of highly oriented pyrolytic graphite (4.4 eV). Surface functionalization which disrupts the π conjugation and introduces surface dipole moments can increase the work function up to 5.1 eV [5.373, 374]. x-Ray photoelectron spectroscopy is well suited for studying MWCNTs and has been used for monitoring MWCNT doping [5.375], purification [5.105], surface functionalization [5.376, 377], and nanoparticle deposition [5.378].

Broadband dielectric spectroscopy is scarcely used on pure MWCNTs. On the other hand, dielectric spectra provide excellent information about MWCNT dispersions either in solution [5.379] or in polymers [5.380]. The most important field of application here is the identification of a percolating MWCNT network [5.381, 382], which is important for, e.g., conductive nanocomposites [5.383] or electromagnetic shielding [5.384, 385].

Terahertz spectroscopy is an emerging new characterization tool today [5.386, 387]. The THz refractive index decreases and the absorption coefficient increases with increasing frequency [5.388]. Since the terahertz

spectrum is sensitive to the **MWCNT** morphology (number of walls, length, etc.), *Parrott et al.* were able to distinguish between two **MWCNTs** on the basis of their THz spectra alone [5.389].

5.3.5 Health and Environmental Issues

There have been an increasing number of scientific publications from the research community at large that address one type of nanomaterial in particular, i.e., carbon nanotubes, and seek to determine if they biologically behave like asbestos; That is, if inhaled, are carbon nanotubes likely to cause irreparable and fatal effects such as those associated with asbestos exposure [5.390]? The effects of asbestos include severe lung fibrosis or scarring and lung cancer, including cancer of the lining of the lungs or pleura called mesothelioma.

More precisely, the major biological processes associated with particle-induced lung injuries are summarized below. After toxic dust inhalation, particles can be either translocated or cleared. Particles that reach the alveolar epithelial surface can stimulate alveolar macrophages (**AM**) but also epithelial cells (**EPITH**) to release several factors attracting leukocytes such as neutrophils (**NEUT**) and lymphocytes (**LYM**) into the lung. The activated alveolar macrophages and neutrophils produce a burden of oxidants and proteases that injure the alveolar wall. Oxidants can also induce cellular and **DNA** damage leading to cancer. Leukocytes also release growth factors and cytokines that stimulate lung fibroblasts to proliferate, with a subsequent accumulation of extracellular matrix. The net result is an expansion of mesenchymal cells and an accumulation of connective tissue matrix which characterize lung fibrosis [5.391]. Details of these processes can be understood by knowing the potential pathways of **CNTs** after inhalation [5.392].

The question of the comparison between carbon nanotubes and asbestos arises for several reasons. Some varieties of carbon nanotubes are similar in shape to asbestos fibers, and like asbestos, some varieties of carbon nanotubes have been shown in laboratory studies to persist in the lungs of laboratory animals. Some animal studies have even shown effects similar to those of asbestos; For example, an in situ study on the fibrogenic activity of carbon black and single-walled carbon nanotubes revealed that only **SWCNTs** caused (i) interstitial fibrotic lesions in the lungs of rats, (ii) significant increases in lung platelet-derived growth factor (**PDGF**) messenger **RNA** (**mRNA**) levels, and (iii) formation of unique carbon bridge structures between alveolar

macrophages in situ. These differences between carbon black nanoparticles and **SWCNTs** suggest that the fibrogenic activity of **SWCNTs** is due to factors that make them unique from carbon black nanoparticles, including their unique shape or the presence of contaminating metal catalysts used in the manufacturing process. Finally, carbon bridge structures that form between macrophages are likely due to the unique structural characteristics of **SWCNTs**.

The question of whether carbon nanotubes pose a toxicological hazard has been investigated since at least 2003 [5.393]. A challenge has been in determining whether carbon nanotube materials used in the workplace have the same characteristics as those associated with biological responses in laboratory studies. Earlier studies used materials with high levels of other forms of carbon such as carbon black and high levels of metal catalyst. *Petersen* and *Henry* recently reviewed the methodological considerations relevant for testing the ecotoxicity of carbon nanotubes [5.394].

Carbon nanotubes can vary widely in diameter, length, number of layers, and structures. They can also vary widely in surface composition, since certain carbon nanotubes may be *coated* with specific metals or other materials in order to perform specific functions. Also, they can clump together or agglomerate, which can affect their potential for settling in the lungs if inhaled, their ability to penetrate the body's membranes and consequently move from the lungs to other organs, and their interaction with cells and tissues. Such variations bring an additional degree of complexity to risk assessment analysis for carbon nanotubes.

In 2005, National Institute for Occupational Safety and Health (**NIOSH**) researchers showed that aspiration of single-walled carbon nanotubes in mice caused progressive fibrosis and granuloma formation [5.395]. (Fibrosis and granuloma reduce the gas-exchange area of the lung, thus making breathing difficult.) It is estimated that 1 month of exposure to carbon nanotubes at the airborne concentration of 5 mg/m³ of air would yield an equivalent dose in workers to that causing fibrosis in the mouse. This 5 mg/m³ concentration is sometimes reported on material safety datasheets as a manufacturer's suggested exposure limit for carbon nanotubes and is based on the permissible occupational exposure limit (**PEL**) for graphite, whose most commonly known use is as a powder for manufacturing pencils. However, the findings reported by **NIOSH** in 2005 suggest that, on the basis of the effects seen in the laboratory studies, it might not be appropriate to use the graphite **PEL** for carbon nanotubes. In fact, **BSI** British

Standards Published Document PD 6699-2, 2007 *Guide to safe handling and disposal of manufactured nanomaterials* suggests setting a benchmark exposure limit for nanoscale fibers longer than 5 μm to one-tenth of the PEL for asbestos, that is at 0.01 fibers per cubic centimeter. However, this benchmark exposure limit, described as a *pragmatic guidance level only*, was not rigorously developed and is derived on the assumption that the hazard potential of the nanoparticle form is greater than the large particle form.

A British study found that long (that is, longer than 20 μm) multi-walled carbon nanotubes exhibit asbestos-like response in the form of injury to the linings of the body cavity in laboratory mice, while short and tangled multi-walled carbon nanotubes do not [5.396]. A Japanese study reported that multi-walled carbon nanotubes were more potent in causing mesothelioma than asbestos in laboratory mice genetically modified to be prone to cancer [5.397].

Even though most contemporary studies focus on the adverse effects of carbon nanotubes in the respiratory tract, it is important to realize that the human toxicity of CNTs in general is also a heavily debated issue today. On the one hand, CNTs are anticipated to revolutionize nanomedicine as drug carriers or nanosurgery devices, but on the other hand, it is also possible that they represent a toxic hazard themselves. The 2010 review of Firme and Bandaru elaborates these questions in detail [5.398]. At the general cellular level the potential targets and payload effects of CNTs are summarized below.

Either receptor-mediated endocytosis or nanopenetration, which is functionalization dependent, are suggested as possible mechanisms for CNT interactions with cells. Although preliminary studies have probed the targeting capability of CNTs vis-à-vis distinct organelles, the mechanism of excretion is as yet unknown.

Unfortunately, in vitro toxicity results for CNTs studied using different cell types remain inconsistent

because all studies used different nanotubes and did not compare CNT toxicity between cell types. A possible intravenous route of CNT circulation after injection is as follows:

1. Contact with flowing red blood cells and plasma, and with vascular endothelium
2. Interaction with contractile fibers of the heart wall
3. Ingestion into alveolar capillaries (lung) and travel through the arteries via the heart
4. Localization to the kidneys for excretion in urine
5. Interaction with cells of the ureter and urethra
6. Delivery close to tumor sites for CNT action (i.e., drug and gene delivery).

As CNTs move into the interstitial space of tissue, excess fluids, along with CNTs, are collected into the (7) lymphatic system and recycled back into the blood to complete the circuit. The effect of CNT interactions at (8) the blood–brain barrier is still unknown.

Interestingly, the final conclusion of Firme and Bandaru on the biomedical applicability of carbon nanotubes is actually positive. They suggest that the safety concerns regarding CNTs can be ameliorated. In this context, it is important to put the known hazards of CNTs into perspective. The average person consumes an estimated 5000 to 300 000 particles/ cm^3 daily due to incidental nanoparticles from the ambient environment. The safe systemic dose of CNTs, if it can be made to conform to such numbers, would then make current toxicity reports on biological risk seem overestimated. Only through a relative comparison can one understand the dangers of functionalized CNT administration against other treatment options. If the queries raised to date can be satisfactorily answered in their favor, then use of CNTs in biomedicine may indeed be feasible. The Janus-like behavior of CNTs in human medicine was elaborated in even more detail in the 2009 review paper of Shvedova et al. on nanotube pulmonary toxicity versus potential medical applications [5.399].

5.4 Selected Applications

Whereas interesting and new scientific results are published continuously in all CNT application fields, these fields are not equally feasible for commercialization [5.400]; For example, single-CNT electronic devices are not even close to mass production, even though they make splendid use of the unique properties of nanotubes. On the other hand, it is very easy to synthesize large quantities of heterogeneous cata-

lysts based on CNT supports, but it is questionable whether the usage of expensive carbon nanotubes is justified over other, cheaper alternative high-surface-area carbonaceous materials.

A possible classification of CNT applications is offered in Fig. 5.2. From the commercial point of view, pursuing goals selected from the top-right quadrant appears to be more justified than going after ones located

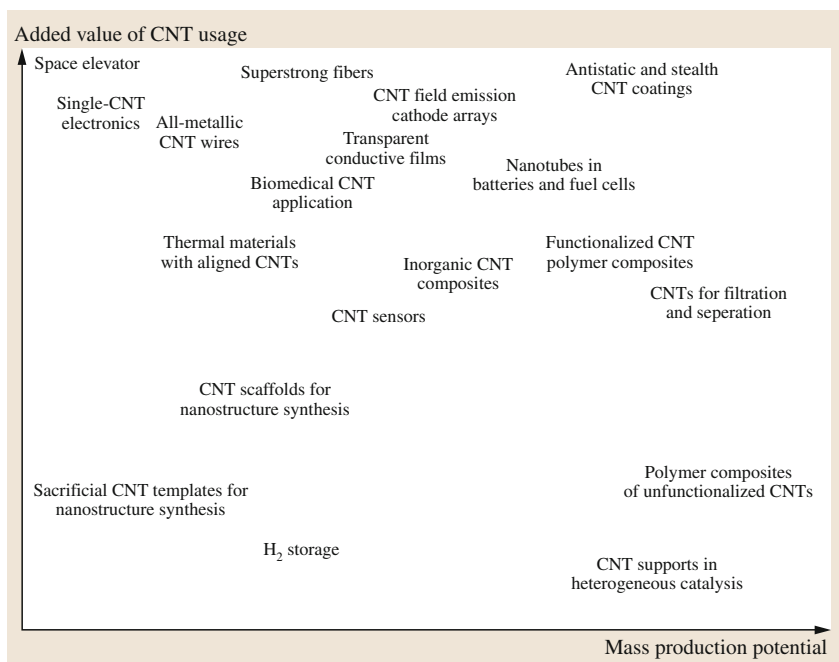

Fig. 5.2 Overview of potential carbon nanotube applications from a commercial feasibility point of view

in the bottom-left quadrant. It is impossible to give full coverage of all MWCNT applications here; therefore, only certain areas are discussed to give an overview of the field.

5.4.1 MWCNT Membranes, Filtration, and Adsorption

Their high aspect ratio as well as chemical and mechanical stability render carbon nanotubes applicable for filtering tasks. In fact, filtration may well be one of the areas where the commercial application of nanotubes is feasible. The simplest CNT filter is a layered self-supporting nanotube film made by the dead-end filtration of a CNT suspension (Fig. 5.3b). We have demonstrated that the specific cake resistance and the gas permeability of the resulting buckypaper are independent of the type of solvent for papers thicker than 150 μm [5.401]. The SEM apparent pore diameter distribution of buckypapers made from CVD-grown MWCNTs is log-normal. The mean pore diameter can be tuned between 24 and 39 nm by changing the length of the nanotubes (Fig. 5.3a) [5.73]. More complex filter architectures can be achieved by adding a second porous layer onto the buckypaper. This was realized by covering the CNT mat with Teflon using pulsed laser deposition (Fig. 5.3c). The diffusion prop-

erties of the resulting structure were governed solely by the porosity of the buckypaper [5.401]. We have measured the effective diffusivity (D_{eff}) of six common laboratory gases through MWCNT buckypaper at a pressure difference of 101 325 Pa. Results fell into the $3\text{--}12 \times 10^{-9} \text{ mol s/kg}$ range and correlated with the kinetic diameter of the gases (Fig. 5.3g) [5.401], in agreement with previous literature results [5.402].

Filter performance can be improved by (i) cross-linking the nanotubes, (ii) controlling the filter geometry precisely or (iii) exploiting selective adsorption phenomena taking place on the nanotube surface. An and Song entangled CNTs by amide bonding and shaped the material into filter form using polydimethylsiloxane (PDMS) molding and vacuum filtering to realize a carbon-nanotube-based microdialysis chip filter [5.403]. Other synthesis alternatives leading to interlinked CNT networks include polyurea functionalization [5.404] and [2 + 1] cycloaddition [5.405].

Pursuing the second alternative for filter enhancement, we were able to construct macroscopic hollow-cylinder filters consisting of radially aligned carbon nanotubes and demonstrated their application potential by eliminating heavy hydrocarbons from petroleum and by filtering *Escherichia coli* bacteria from water [5.406]. Chen and Wang tested the nicotine and tar removal efficiency of oxidized carbon nanotube filters

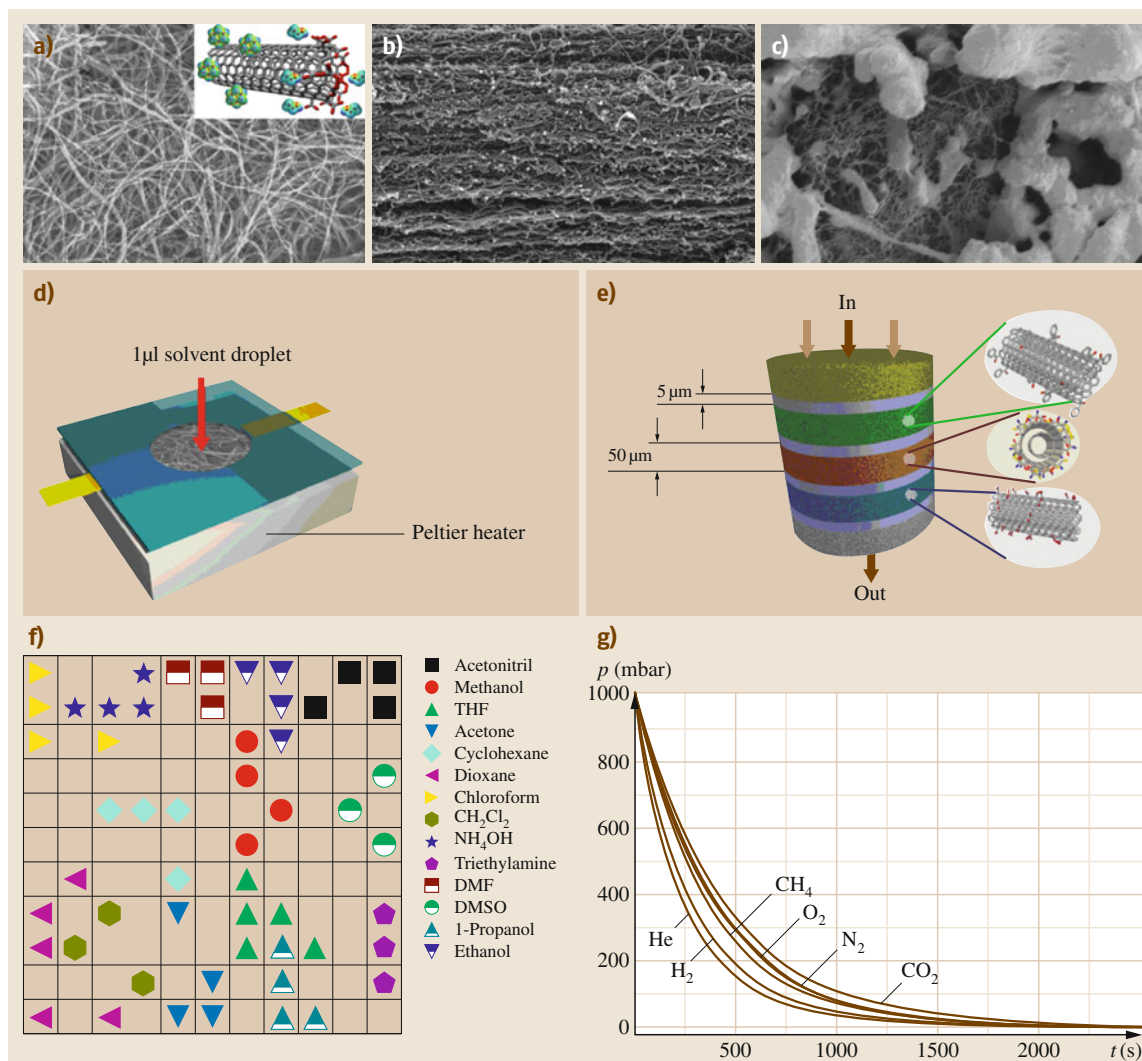

Fig. 5.3a–g Top (a) and side (b) SEM views of a MWCNT buckypaper. The *inset* in (a) demonstrates the selective adsorption of cyclohexane on unfunctionalized and ethanol on functionalized nanotube surfaces. (c) Laser-ablated porous Teflon coating on buckypaper. (d) Conceptual devices for measuring evaporation profiles and (e) multi-gas sensor response using buckypaper. (f) Kohonen clustering of certain organic solvents based on their evaporation profile (THF: tetrahydrofurane; DMF: dimethylformamide; DMSO: dimethyl sulfoxide) and (g) gas permeability of a MWCNT buckypaper for several common laboratory gases

from mainstream cigarette smoke and suggested that 20–30 mg CNT per cigarette could be enough to remove most of the nicotine and tar [5.407]. Although the price of carbon nanotubes is dropping continuously, the cheap commercial availability of nanotube-only filters may still be well in the future. However, highly cost-effective devices can be realized by combining

the superior filtering/adsorption abilities of CNTs with, e.g., proven polymer membrane technology. MWCNT-coated cellulose fiber filters exhibited filtration efficiencies exceeding 99% for airborne fine particles even at very low (0.07 mg/cm²) nanotube coverages [5.408]. Basheer et al. constructed a micro solid-phase extraction device by heat-sealing 6 mg MWCNTs into a porous

polypropylene membrane sheet. The device showed superior organophosphorus pesticide enrichment performance in sewage sludge sample analysis [5.409]. The applicability of carbon nanotubes in solid-phase extraction units was confirmed for polybrominated diphenyl ethers [5.410], benzodiazepine residues [5.411], and drugs spiked in urine [5.412] as well.

MWCNTs show some promise as heavy-metal ion adsorbents. Since the sorption is heavily dependent on the nanotube functionalization, temperature, pH, ionic strength of the solution, etc., it is possible to tune MWCNT adsorbents towards selected ions. The sorption behavior of ^{243}Am [5.413], Ni^{2+} [5.407], Pb^{2+} [5.414–416], Cu^{2+} [5.415–417], Zn^{2+} [5.415, 416], and Cd^{2+} [5.416] on MWCNTs has been published so far. Moreover, MWCNTs can be combined with MnO_2 to remove Pb^{2+} and Cd^{2+} [5.418], with titanate nanotubes to remove Pb^{2+} and Cu^{2+} [5.419], and with iron/iron oxide to adsorb Ni^{2+} , Sr^{2+} , and Cu^{2+} [5.420].

There is a huge and largely untapped potential in exploiting selective adsorption phenomena taking place in the pores of buckypaper made of functionalized CNTs. Carbon nanotubes are inherently somewhat hydrophilic, with a water contact angle of less than 86° [5.421]. Moreover, the widely utilized oxidative purification method renders the nanotube surface definitely hydrophilic, as could be demonstrated by measuring adsorption excess isotherms in the cyclohexane–ethanol–nanotube system (Fig. 5.3a, *inset*) [5.121]. A truly hydrophobic CNT surface is best achieved by high-temperature annealing of a purified nanotube sample. The selectivity of the adsorption phenomenon can be enhanced by taking a step further than hydrophilic–hydrophobic balance and increasing the affinity of the nanotube membrane towards a specific molecule via covalent functionalization [5.422].

Recently, we examined the adsorption and evaporation behavior of certain liquid analytes in MWCNT membranes in detail [5.423]. We found that the electrical resistance of MWCNT buckypaper as a function of time changes in a pattern characteristic of a liquid dropped onto a heated nanotube membrane (Fig. 5.3d). The measured *evaporation profiles* of the analytes could be classified correctly by a Kohonen self-organizing map-type artificial neural network (Fig. 5.3f), therefore making qualitative identification of liquid analytes possible from sample amounts comparable to typical gas chromatography (GC) experiments. It should be noted here that carbon nanotubes were also tested successfully as conventional stationary phases of GC columns

by several groups [5.424, 425]. For a complete review of CNTs in analytical science we refer to Valcarcel et al. [5.426].

5.4.2 MWCNTs in Catalysis

Their relatively high specific surface area (typically 100–500 m^2/g) and heat stability render carbon nanotubes a suitable support material for heterogeneous catalysis. Even though the idea itself [5.427] was suggested as early as 1994, research in this direction was sporadic because of the high cost of CNTs. We refer to the review of Serp et al. [5.428] for developments until 2003 and to Georgakilas et al. for a review of the rich chemistry of attaching metallic and semiconductor nanoparticles to carbon nanotubes, a prerequisite for granting them catalytic activity [5.204].

The fundamental issue when using CNTs as heterogeneous catalytic supports is producing a sufficiently pure nanotube sample. Some important scientific achievements of the last few years have made it possible to grow very clean nanotubes [5.429]; however, these methods have not yet matured to an industrial production level. At a commercial scale, carbon nanotubes are solely manufactured today by variations of the catalytic chemical vapor deposition method. The resulting samples are considered *clean* if their catalyst impurity (typically transition metals iron or cobalt) content is below 2 wt%, which is actually well within the metal loading range of several commercial supported catalysts used by the chemical industry. Sometimes the metal content cannot be removed even by very aggressive purification schemes [5.79]. Even though the metal contamination is usually inactivated by the covering carbonaceous layers, it is considered bad practice in heterogeneous catalysis to work with a support containing an ill-defined amount of potentially active species in ill-defined chemical condition.

It is also debatable from the application point of view whether heterogeneous catalysis is indeed a field where the high cost of using carbon nanotubes instead of other supports is justified today. Noble metals supported on CNTs certainly perform well in fuel-cell applications [5.430] because of the low charge-transfer reaction resistance of the interface and also in traditional C=C bond hydrogenation reactions [5.431]. Carbon nanotube supports are generally resistant to coke formation because of their low acidity [5.432], but this statement holds for other carbon species as well. On the other hand, Pt and/or Pd catalysts supported on CNTs do not appear to outperform the correspond-

Fig. 5.4a,b TEM images of a tube-on-tube MWCNT branch synthesized by the double CCVD method developed by Kiricsi et al. (a) and (b) depict a typical Y branch and a typical parent-child relationship, respectively. (After [5.435])

ing carbon black or carbon microfiber supports with comparable noble-metal nanoparticle dispersions in continuous industrial hydrogenation/dehydrogenation processes [5.433]. The most promising development in this field is the recent discovery of a huge synergetic effect between Rh nanoparticles confined inside carbon nanotubes and the nanotube host itself in the conversion of CO and H₂ to ethanol [5.434].

Papers on using carbon nanotube supports for other mainstream heterogeneous catalytic processes such as

reforming, hydrodesulfurization, isomerization, oxidation, and Fischer–Tropsch synthesis [5.436–438] are available but not abundant. Moreover, these reports have yet to prove that the usage of carbon nanotubes truly improves the performance of the already well-known active functions.

Carbon nanotubes have a morphological advantage over traditional porous supports such as carbon black or silica: in a CNT matrix there are no bottled pores or dead ends [5.439]. Therefore, the full surface of the nanotube forest is available for reaction, and the pressure drop on the catalyst bed can be kept very low, which in turn means that theoretically the reactor could run at very high space velocities. The catalytic community is still waiting for a breakthrough which would exploit this advantage on an industrial level.

There is one heterogeneous catalytic application, however, where the use of carbon nanotubes is a prerequisite for success, i. e., growing CNTs on a CNT support to obtain a branched nanotube network. This method was developed by us and is characteristically different from the one-step reactions tuned towards a high yield of Y-junctions [5.440]. We discovered that it is possible to impregnate chemical vapor deposition (CVD)-grown carbon nanotubes by a second transition-metal precursor molecule and repeat the CVD reaction [5.435] to get an interconnected nanotube network assembled through metal nanoparticle joints (Fig. 5.4). The diameter ratio of the parent and the child nanotube can be controlled by tuning the CVD reaction conditions.

5.4.3 MWCNT Composites

MWCNTs are extensively used and tested as polymer additives to improve mechanical properties, fire retardancy, electromagnetic shielding, thermal conductivity, etc. The majority of MWCNTs commercially produced today are purchased by polymer composite manufacturers and used in end-user products such as golf clubs, boat hulls, and structural plastics. Some of the best MWCNT composites available today do not use the MWCNTs as primary reinforcement elements; rather, the function of the nanotubes is to promote load transfer from the matrix to the reinforcement material (e.g., a Kevlar or carbon fiber textile). The following factors must be kept under rigorous control in order to create high-performance MWCNT–polymer nanocomposites:

1. Pretreatment of the nanotubes [5.441]
2. Disentanglement and homogeneous distribution of the nanotubes in the matrix [5.442]

3. Orientation of the nanotubes in the composite [5.443, 444]
4. High-quality synthesis of the polymer matrix itself, i. e., no air bubbles, correct usage of additives, etc.

It is actually quite difficult to meet all these criteria, which is probably the reason why the quality of MWCNT–polymer nanocomposites reported in the literature is very heterogeneous. Polymer nanocomposites are regularly reviewed in detail [5.445–455].

Inorganic composites of carbon nanotubes is a field where rapid expansion took place recently. This is because several widely used technological and construction materials (ceramics, semiconductors, steel) are processed under such demanding conditions that it is difficult to find a carbon-based modifier compatible with the technology. Their exceptional mechanical properties, heat stability, and low chemical reactivity render carbon nanotubes suitable candidates for such a role. Similarly to the case of CNT-reinforced polymers [5.446] and CNT-based biomaterials [5.456], the biggest challenge is interfacing the nanotubes to the inorganic matrix [5.457, 458]. MWCNT–SnO₂ composites are utilized as sensors [5.213, 214, 459, 459] and Li⁺ battery anodes [5.215, 460–462], MWCNT–TiO₂ materials as photocatalysts [5.210, 463, 464], and MWCNT–ZnO as promoted catalyst [5.465], photocatalyst [5.466, 467], or sensor [5.468, 469].

We have shown that mixing MWCNTs into the precursor solution of the mesoporous silicate MCM-41 results in a composite material with tailored pore structure and controlled surface chemical properties [5.470]. It was also shown by Raman spectroscopy and x-ray photoelectron spectroscopy (XPS) that there exists a special interface region between nanotubes and SnO_x or VO_x in their sol–gel-derived composites [5.471]. A 5–10 wt% CNT loading is enough to improve the electrical conductivity of a ceramic matrix by 5–8 orders of magnitude, and it generally improves the mechanical properties of ceramics as well [5.472]. However, a lot remains to be discovered in this field; For example, adding 10 wt% MWCNTs to a borosilicate glass matrix will worsen the load-bearing but improve the wear-resistant properties of the glass [5.473].

Little attention has been devoted to nanotube–metal composites in the literature so far, even though the possibility of synthesizing such structures has been demonstrated for titanium [5.474], copper [5.475], cobalt [5.476], aluminum [5.477], magnesium [5.478], and iron [5.479]. This latter finding is especially interesting, since in a recent paper Paufler et al. reported

on the discovery of carbon nanotubes in a 17th century Damascus steel sword [5.480]. We expect to see major advances in the applications of CNT–metal composites in the coming years.

5.4.4 Other Selected MWCNT Applications

The excellent thermal conductivity of MWCNTs can be exploited in creating nanotube heat sinks, thermal interface materials [5.481], and heat-conductive polymer nanocomposites [5.482]. MWCNT films can be used as scalable temperature sensors with temperature coefficient of resistance around $-7 \times 10^{-4} \text{ K}^{-1}$ for unmodified films [5.483]. Smajda et al. demonstrated that the temperature sensitivity of MWCNT buckypapers can be improved by depositing pyroelectric crystals (e.g., CsNO₃ or LiNbO₃) on the nanotubes [5.484].

Vertically aligned MWCNT arrays can serve as directional adhesives mimicking the famous gecko foot-hair effect [5.485, 486].

MWCNTs are very well suited to serve as a basis for biosensors, because they are electrically conductive, can be functionalized, and can act as an immobilization matrix formed into diverse macroscopic shapes of controlled porosity [5.487, 488]. MWCNT-based biosensors have been created for the detection of, e.g., reduced nicotinamide adenine dinucleotide (NADH) [5.489], glucose [5.490], organophosphorus nerve agents [5.491] and pesticides [5.492], cholesterol [5.493, 494], H₂O₂ [5.495, 496], phenolics [5.497, 498], serotonin and dopamine [5.499], acetaminophen and tyramine [5.500], tetracycline [5.501], and even bacteria [5.502].

Early in the nanotube era, MWCNTs were seriously considered for pharmaceutical applications, including cell membrane channels and drug delivery systems [5.168, 503–506]. Even though such applications are technically possible, the current controversies around the human health effects of carbon nanotubes will make a MWCNT-based human drug delivery breakthrough very difficult in the near future. On the other hand, MWCNTs promote cell adhesion and proliferation (e.g., L-929 mouse fibroblast cells and C2C12 mouse myoblastic cells). Therefore, MWCNTs may play an important role in future tissue engineering and neural cell scaffolding applications, which may eventually lead to more complex bionanotechnological systems [5.507–511].

We conclude this chapter by discussing some electronic applications of MWCNTs. Due to the differences between the band structure of SWCNTs and MWCNTs

and also because of the lack of reliable bandgap engineering and separation procedures for MWCNTs, individual-tube-based device applications, which are so important for SWCNTs, are not very relevant for multi-walled carbon nanotubes. Rather, their electronic applications exploit their light weight, good conductivity, relatively low price, low growth temperature, high current tolerance, and field-emission properties. MWCNTs are therefore utilized as electric cables

and interconnects [5.512–514], transparent conductive films [5.515–517], Li⁺ ion battery electrodes [5.518–524], field-emission light sources [5.525, 526], inkjet-printed circuits [5.527, 528], and sensors [5.529]. A stimulating recent development is the report of a very high-performance lithium ion capacitor based on NiO-nanoparticle-containing nitrogen-doped MWCNTs that features 3500 mAh/g capacity and cycle life greater than 10 000 times [5.530].

Modified Car

6. Modified Carbon Nanotubes

Aarón Morelos-Gómez, Ferdinando Tristán López, Rodolfo Cruz-Silva, Sofia M. Vega Díaz, Mauricio Terrones

It is well known that carbon nanotubes possess outstanding electrical and mechanical properties, and if they are modified these properties can be improved or other novel characteristics can appear. In addition, these modified carbon nanotubes, being different from their pure counterparts, now require additional studies to assess their toxicity and biocompatibility.

Generally speaking, carbon nanotubes can be classified as single-, double- or multi-walled, and each type can be modified; For example, these tubular structures can be doped with foreign atoms, incorporate structural defects, and/or be functionalized with different molecules. These local modifications greatly modify their electronic and chemical properties, and can be understood by using a variety of microscopy and spectroscopy techniques.

In Sect. 6.1, we describe the general concepts and synthesis for the main doping types. In Sect. 6.2, we focus on the different types of defects that can be introduced into nanotubes so as to modify their physicochemical properties. Section 6.3 discusses the categories of nanotube chemical functionalization and their resulting effects. The electrochemical properties of modified carbon nanotubes are an important topic that needs further investigation, and Sect. 6.4 reviews the latest advances in this area. The characterization techniques mainly used to study modified carbon nanotubes are reviewed in Sect. 6.5. Some applications of modified carbon nanotubes are described in Sect. 6.6. Finally, aspects of the toxicity and biocompatibility of modified carbon nanotubes are presented in Sect. 6.7. The chapter finally provides an outlook and perspectives in the field.

In recent years, it has been demonstrated that modified carbon nanotubes exhibit novel and fascinating

properties that could be used in the fabrication of composites, electronic devices, and biomedical applications.

In order for them to be used in these devices and applications, it is important to make them more compatible with different molecules, atoms, cells, or even clusters.

Although great advances in carbon nanoscience and nanotechnology have been achieved over the last 20 years, there is still more work to be done, and this chapter intends to present current research so that novel ideas and applications can be developed based on the modification of carbon nanotubes (CNTs).

The nanocarbon world is vast and novel. Carbon nanostructures have appeared over the last two decades. Nanocarbon cages (also known as fullerenes) were first observed in 1985 [6.2] and synthesized in bulk in 1990 [6.3]. Soon afterwards, other nanocarbon forms known as nanotubes were identified by *Iijima* [6.4], although some previous observations in the 1970s reported synthesis of carbon nanotubes using the chemical vapor deposition method developed by *Endo* et al. [6.5]. More recently and at the beginning of this century, flat

layers of graphene were successfully isolated [6.6] and their electronic properties were measured [6.7,8]. The search for new forms of carbon continued, and very recently, graphene nanoribbons were also synthesized and produced using different routes [6.9]. Therefore, it is clear that carbon is extremely versatile and can be shaped into any nanomorphology.

To date, the most prolific scientific carbon field has been dedicated to carbon nanotubes. However, graphene and graphene nanoribbons are also gaining importance day by day. In particular, carbon nanotubes possess fascinating electronic, optical, and mechanical properties depending on their geometry (diameter and chirality) [6.10, 11]. These tubular structures can be categorized into three groups as a function of the number of concentric layers they contain (Fig. 6.1): single-walled carbon nanotubes (SWCNTs), double-walled carbon nanotubes (DWCNTs), and multi-walled carbon nanotubes (MWCNTs). All these tubular cat-

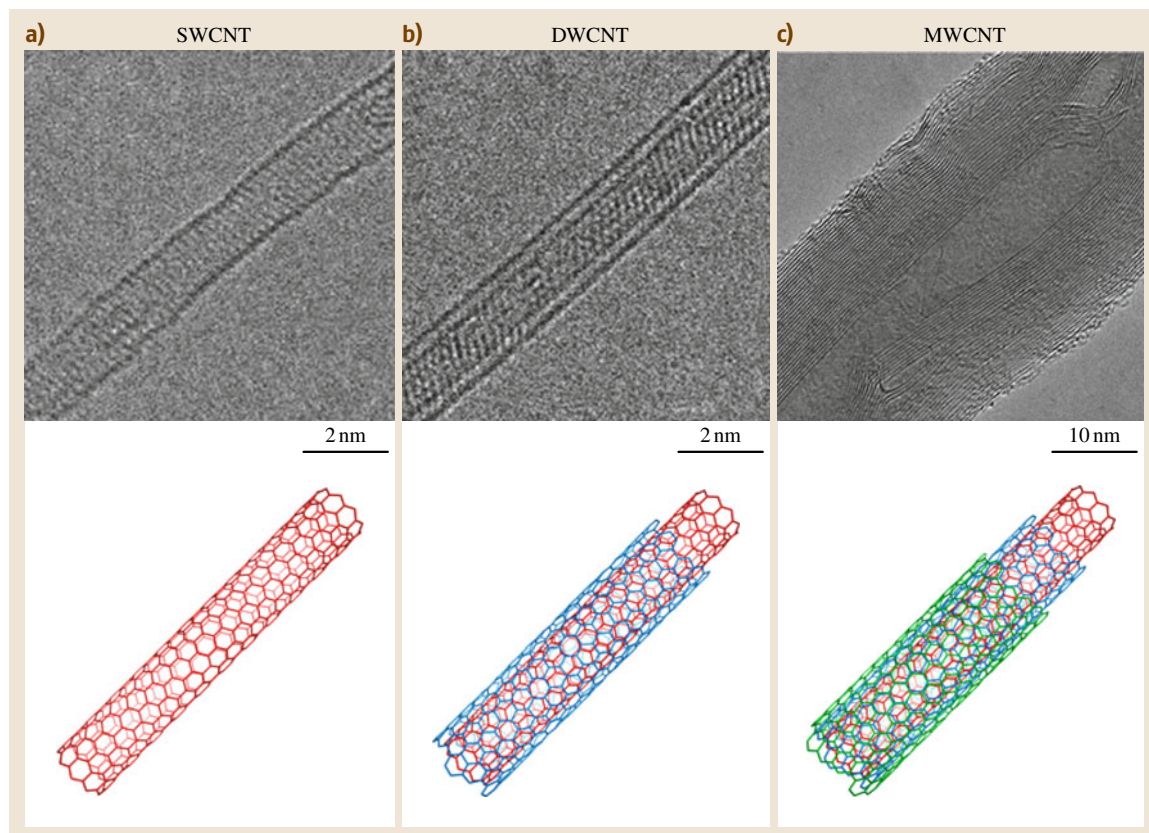

Fig. 6.1a–c High-resolution transmission electron microscopy (HRTEM) images and molecular models of: (a) single-walled (SWCNT), (b) double-walled (DWCNT), and (c) multiwalled (MWCNT) carbon nanotubes (after [6.1])

egories are relatively stable and can exhibit extreme chemical surface inertness, which can be modified by introducing defects or by anchoring moieties in their crystalline structure. This chemical modification process can occur through three main routes (Fig. 6.2):

1. Nanotube doping
2. Defect introduction and
3. Nanotube functionalization.

These routes open up the opportunity to tailor the electronic, vibrational, chemical, and mechanical properties of carbon nanotubes.

We will also show in this chapter that modified carbon nanotubes possess outstanding properties when compared to pure carbon nanotubes, and it is foreseen that these systems will develop further nanotube science, and will eventually transform the potential applications of carbon nanotubes into real-world technology.

6.1 Doped Carbon Nanotubes

In this section we review three main doping categories: (a) exohedral doping or intercalation, (b) endohedral doping or encapsulation, and (c) in-plane or substitutional doping. By definition, in-plane doping is a covalent functionalization, whereas the endohedral and exohedral kinds of doping can be either covalent or noncovalent functionalization (Fig. 6.3). Due to the

nanotube curvature, it is expected that exohedral covalent functionalization will be more favorable when compared with the endohedral counterpart because the outer surface (convex) is more reactive than the inner surface (concave). Using surface science terminology, covalent and noncovalent functionalization are also termed chemisorption and physisorption, respectively.

Fig. 6.3a–c Molecular models illustrating the possible sites and different doping types in carbon nanotubes: (a) exohedral doping or intercalation, (b) endohedral doping or encapsulation, and (c) in-plane or substitutional doping

6.1.1 Endohedral Doping

The possibility of filling the core (*endohedral doping*) of these one-dimensional (1-D) structures with atoms or molecules is attractive for scientists because both storage and transport of molecular species at the nanoscale are of great interest, especially in biology for drug delivery and as models for biochemical processes. This field started with the theoretical work of *Pederson* and *Broughton* [6.12] claiming the nanocapillarity of carbon nanotubes. From the experimental standpoint, *Ajayan* et al. [6.13] were the first to report the filling of MWCNTs with lead or lead oxide, by heating the tubes in air together with metallic lead. There is extensive work related to the filling of carbon nanotubes, which has been reviewed elsewhere [6.14–16].

Filling of carbon nanotubes has been of historical importance in nanotube science. It was the attempt to fill the core of MWCNTs with pure transition metals such as Ni, Co, and Fe that resulted in the production of SWCNTs using the arc discharge technique [6.17, 18]. Five years later, the first reports relating to the successful filling of SWCNTs with C₆₀ molecules were presented by *Smith* et al. [6.19] and *Sloan* et al. [6.20]. The remarkable properties of these endohedrally doped systems led to fast development in use of the 1-D structure of SWCNTs to prepare a large variety of filled nanotube systems (Fig. 6.3b). The natural attempt was to use the unique 1-D tubular morphology as the template for preparing a new generation of very small-diameter wires or to prepare quasi-1-D superconductors using alkali metals as fillers. Heavy metals such as Ru, Bi, Au, Pt, Pd, and Ag have also been inserted in the nanotube cavity [6.20, 21]. In addition, a variety of other metals have been filled within MWCNTs, such as Re, Pb, Cr, Ge, Cu, FeCo, FePt, FeNi, and Fe₃C [6.22–35]. In addition, different compounds such as halides and oxides have also been introduced into SWCNTs [6.36].

The discovery of C₆₀@SWCNTs (also called fullerene peapods; Figs. 6.3b, 6.4a) is another very important advance in carbon nanotube science. The control and high yield of C₆₀ filling could lead to double-walled carbon nanotubes (DWCNTs) after heat treatments (Fig. 6.4b). Furthermore, this system allowed the observation in real time using an electronic microscope of nanoscale phenomena such as dimerization, diffusion, and coalescence [6.37, 38]. Subsequently, 1-D crystals were synthesized using encapsulation of metallofullerenes [6.39].

Bundles of as-prepared carbon nanotubes (SWCNTs, DWCNTs or MWCNTs) can serve as a host lattice

Fig. 6.4a,b HRTEM images of: (a) peapods, consisting of C₆₀ molecules encapsulated inside SWCNTs, and (b) a DWCNT resulting from heat treatment of peapod samples at 1700 °C in Ar atmosphere (courtesy of M. Endo, T. Hayashi, H. Muramatsu)

for different chemical moieties. The electronic properties can be tailored by doping with electron-donating or electron-accepting guest atoms and small molecules, which reside in the interstitial channels. Endohedral doping is expected to substantially increase the density of free charge carriers (electrons or holes) and thereby enhance the electrical and thermal conductivity in SWCNT bundles.

6.1.2 Exohedral Doping

Intercalated alkali metal atoms (*exohedral doping*) act as electron donors, and this charge transfer weakens the C–C bonds in the SWCNTs, as electrons have been known to soften the C–C bond in all sp²-bonded carbon materials [6.40, 41]. Acceptor halogens (e.g., CHCl₃, Br₂) were found to stiffen the C–C bonds. This kind of

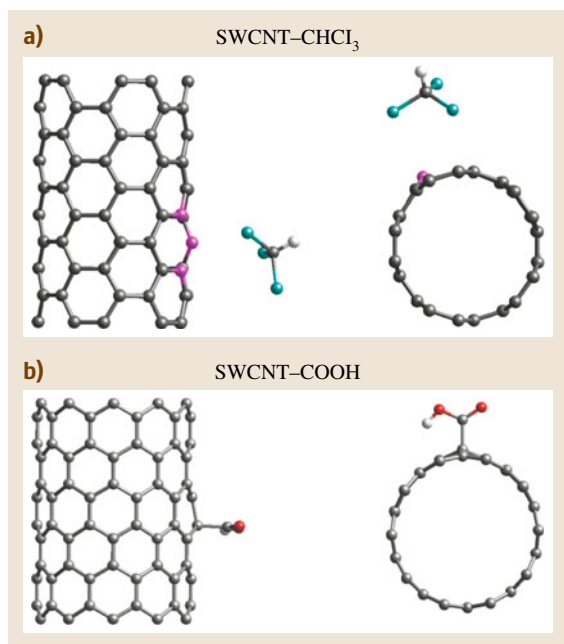

Fig. 6.5a,b Molecular models: (a) CHCl_3 molecule physisorbed to a N-doped SWCNT (side view and cross section), (b) COOH group chemisorbed to a SWCNT (side view and cross section; courtesy of E. Gracia-Espino)

doping is noncovalent, and such carbon nanotube samples can be easily undoped by heat treatments at high temperatures. The atomic structure of the nanotubes is not affected in this process (Fig. 6.5a), but the electronic structure is strongly affected.

Exohedral doping can also be covalent (functionalization), which can modify the nanotube wall to a great extent depending on the concentration of the dopant molecules. There are several routes for covalently attaching moieties onto the surface of carbon nanotubes, but one of the most simple covalent functionalization is carboxylation of the nanotubes (Fig. 6.5b). The charge plots for the local densities of states coming from the half-occupied levels indicate that charges are mainly lo-

cated around the functional groups (Fig. 6.5b) [6.42]. The carboxylic acid group (COOH) is considered the prototype chemical group for achieving covalent functionalization of carbon nanotube because the carbon atom is covalently bonded to the tube while the $-\text{OH}$ group can be exchanged for other chemical groups using standard chemical reactions via a coupling agent. This approach allows one to attach more complex molecules such as amino acids and DNA, and other groups such as amine and amide [6.43].

Optical absorption spectra of doped SWCNT thin films can provide insight into which electronic states are primarily influenced by the charge transfer interaction with the dopants. Kazaoui et al. [6.44] have separately monitored the doping behavior of semiconducting and metallic SWCNTs in a combined optical absorption and direct-current (DC) resistance measurement study. Both electron acceptors (Br_2 , I_2) and donors (K, Cs) were used as dopants, with controlled stoichiometry. Disappearance of absorption bands at 0.68 and 1.2 eV (assigned to semiconductor SWCNTs) and at 1.8 eV (assigned to metallic SWCNTs) in pristine SWCNTs with a concomitant decrease in the electrical resistance upon doping has been attributed to electron depletion from, or filling of, specific bands in semiconducting or metallic SWCNTs.

6.1.3 In-Plane Doping

Both structural and electronic properties of the nanotubes are highly affected by substitutional (*in-plane*) doping. In this process one or more heteroatoms (defects) are added to the nanotube lattice (Fig. 6.3c), thus breaking the translational symmetry of the lattice. Both the number of electrons and the size of the heteroatom play an important role in determining the physical properties (structure, morphology, and electronic) of the doped structures. In the following section we discuss in detail this doping process, focusing mainly on boron- (B-), nitrogen (N-), boron-nitrogen- (BN-), and phosphorous-nitrogen- (PN-) doped carbon nanotubes.

6.2 Defects in Carbon Nanotubes

Defects are crucial in tailoring the physicochemical properties of carbon nanotubes. They can significantly affect the morphology and functionality of tubes. Unfortunately, it is still extremely difficult to identify accurately and quantitatively the type of defects contained in carbon nanotubes (SWCNTs and

MWCNTs). The most common defects are classified as:

1. Structural defects
2. Topological defects or heptagon-pentagon pair (Thrower-Stone-Wales)-type transformations

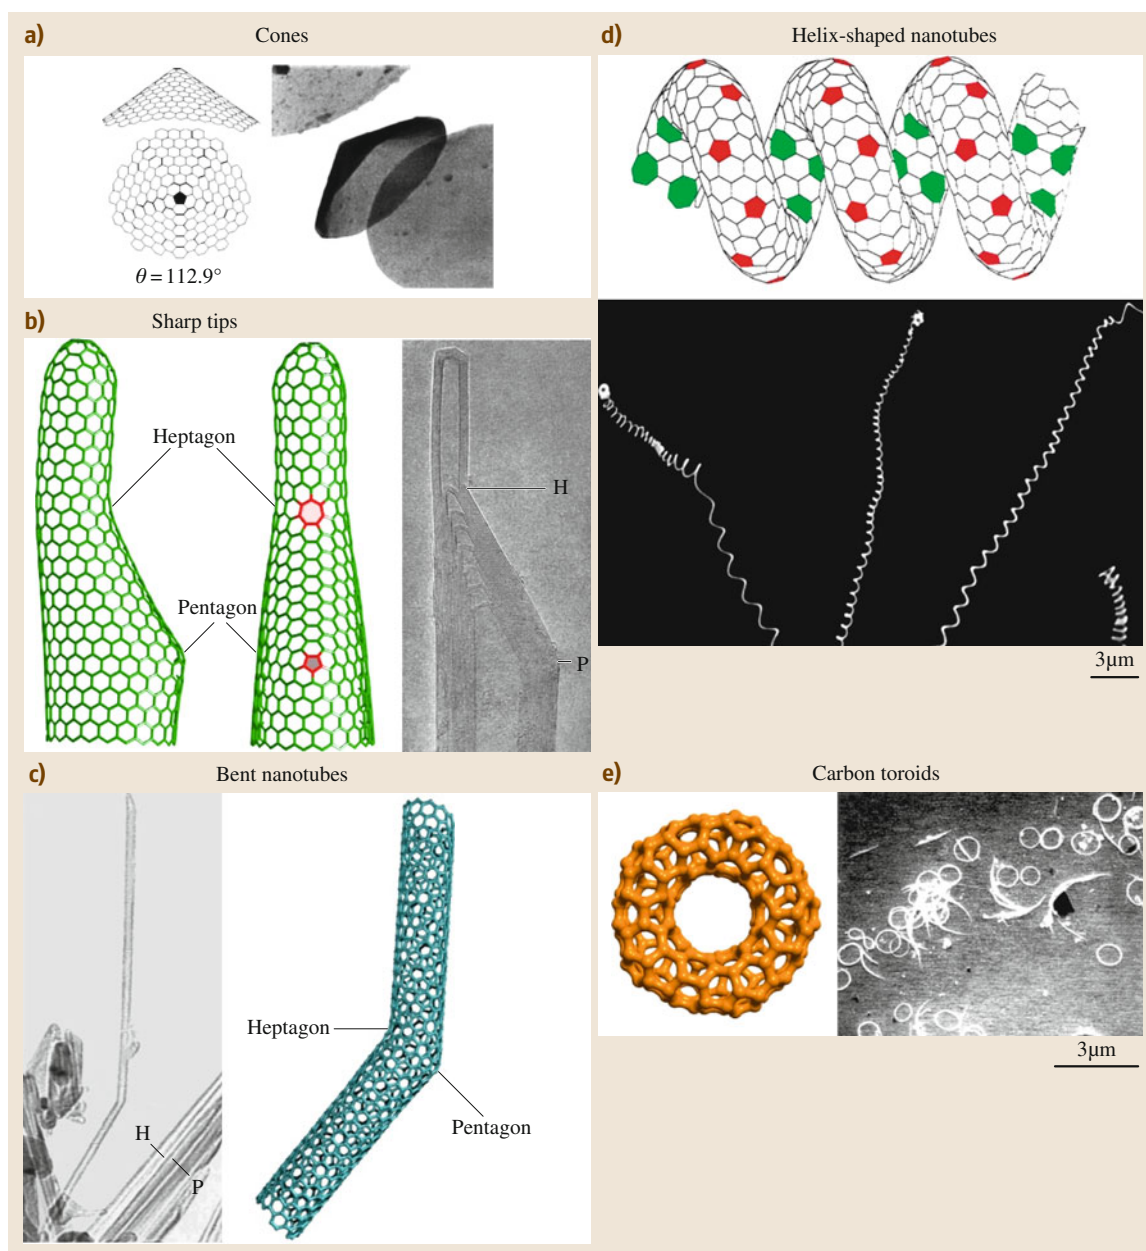

Fig. 6.6a–e TEM images and molecular models of different types of structural defects in sp^2 -hybridized carbon. (a) Graphitic cone constructed by adding one pentagon in graphene, a molecular model and an experimental TEM image of such cones are shown for clarity (model courtesy of M. Endo, experimental image courtesy of T.W. Ebbesen; Krishnan et al. [6.45]). (b) High-resolution image of a nanotube tip displaying the influence of a pentagon and heptagon. The image shows the molecular models, and a HRTEM image of such structure has been reported (after [6.46]). (c) TEM image of a 30° bent MWCNT and molecular model of a bent nanotube created by adding a pentagon–heptagon pair. (d) Molecular model of a helix-shaped CNT showing the presence of pentagons and heptagons (after [6.47]) and experimental images of carbon helices produced by the CVD process of triazine over cobalt oxide substrates. (e) Molecular model of a toroidal carbon and experimental SEM image of toroidal carbons obtained by the IBM group (after [6.48])

3. Narrow-diameter tubes or collapsed tubes
4. Interstitials, edges, and adatoms (Fig. 6.6).

It is noteworthy that heptagons, pentagons, heptagon-pentagon pairs, and collapsed tubes preserve the sp^2 -hybridized lattice, whereas interstitials, adatoms, and vacancies do not. It is envisaged that defects could be controlled so as to design novel types of morphologies in carbon nanotubes, including helicoidal tubules, toroids, etc. (Fig. 6.6). These structures will then possess specific sites that could be very sensitive to different molecules or certain polymer chains:

1. *Structural defects* are imperfections that significantly modify the overall curvature of the tube.

These defects include pentagons, heptagons, and octagons, and are embedded in the sp^2 -hybridized carbon lattice; for example, if an individual pentagon is embedded in a graphene sheet, a nanocone is obtained (Fig. 6.6a). It has also been demonstrated that heptagons introduce negative curvature and pentagons positive curvature to a graphene sheet (Fig. 6.6b). A bent nanotube exhibiting a 30° angle could also be explained by the presence of a pentagon on one side and a heptagon on the opposite side (Fig. 6.6c). It is clear that the reactivity of pentagons, heptagons or octagons with specific acceptor or donor molecules will be different, and further research is needed to determine their interactions from a theoretical and experimental standpoint (Fig. 6.6).

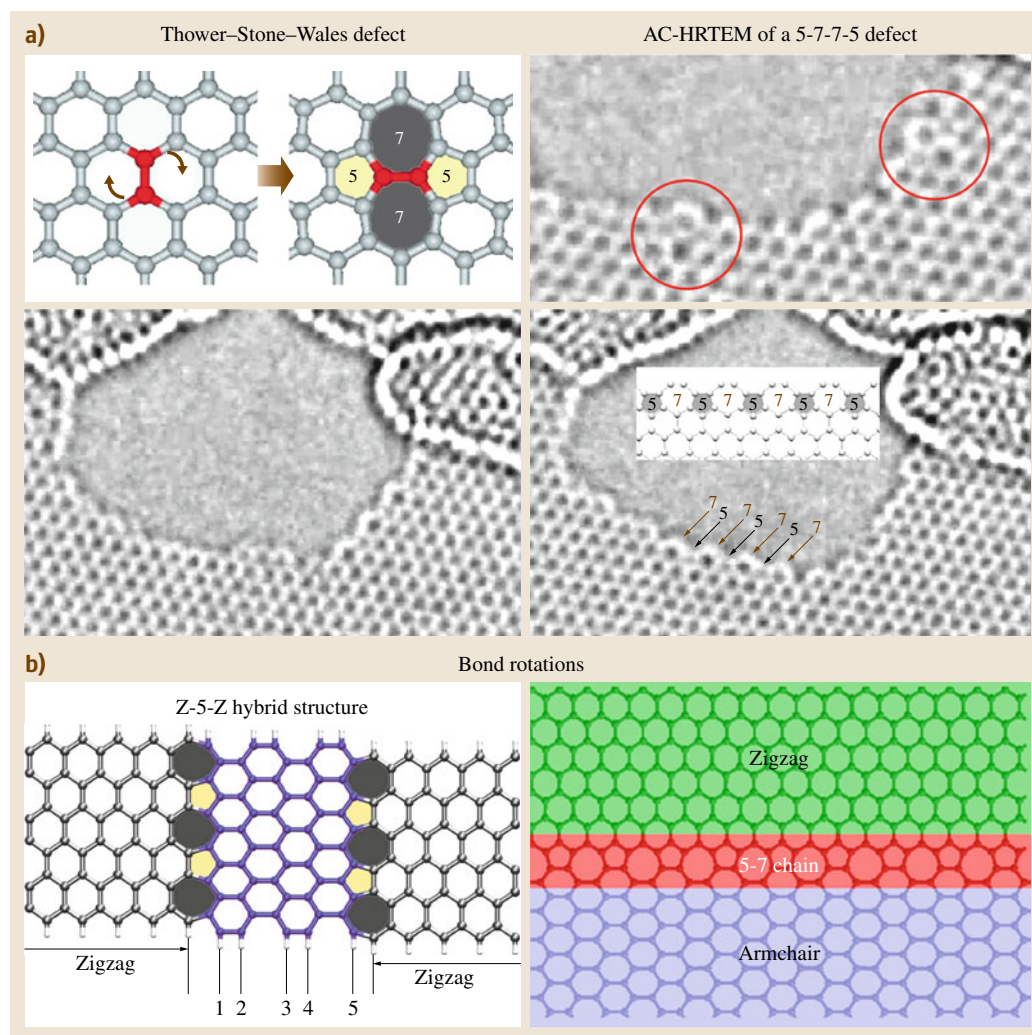

Fig. 6.7 (a) Molecular model of the Thower–Stone–Wales defect transforming four hexagons into two pentagons and two heptagons. Next and below the model, HRTEM images showing experimentally created 5-7-7-5 defects and 5-7-5-7-5-7-5-7 lines (HRTEM images from [6.49]). (b) Molecular models of hybrid graphene ribbons connecting a zigzag ribbon with an armchair ribbon

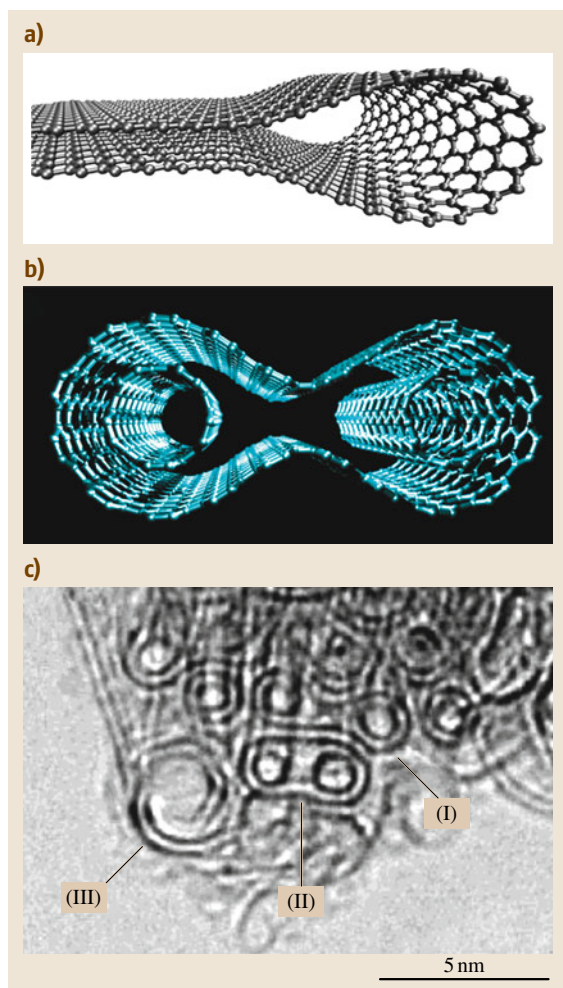

Fig. 6.8 (a) Molecular model of one segment of a collapsed CNT showing high strain and deformation of the p_z orbital. (b) Collapsed nanotube with two narrow-diameter tubes inside (binocular-like structure). (c) HRTEM image of the model shown in (b)

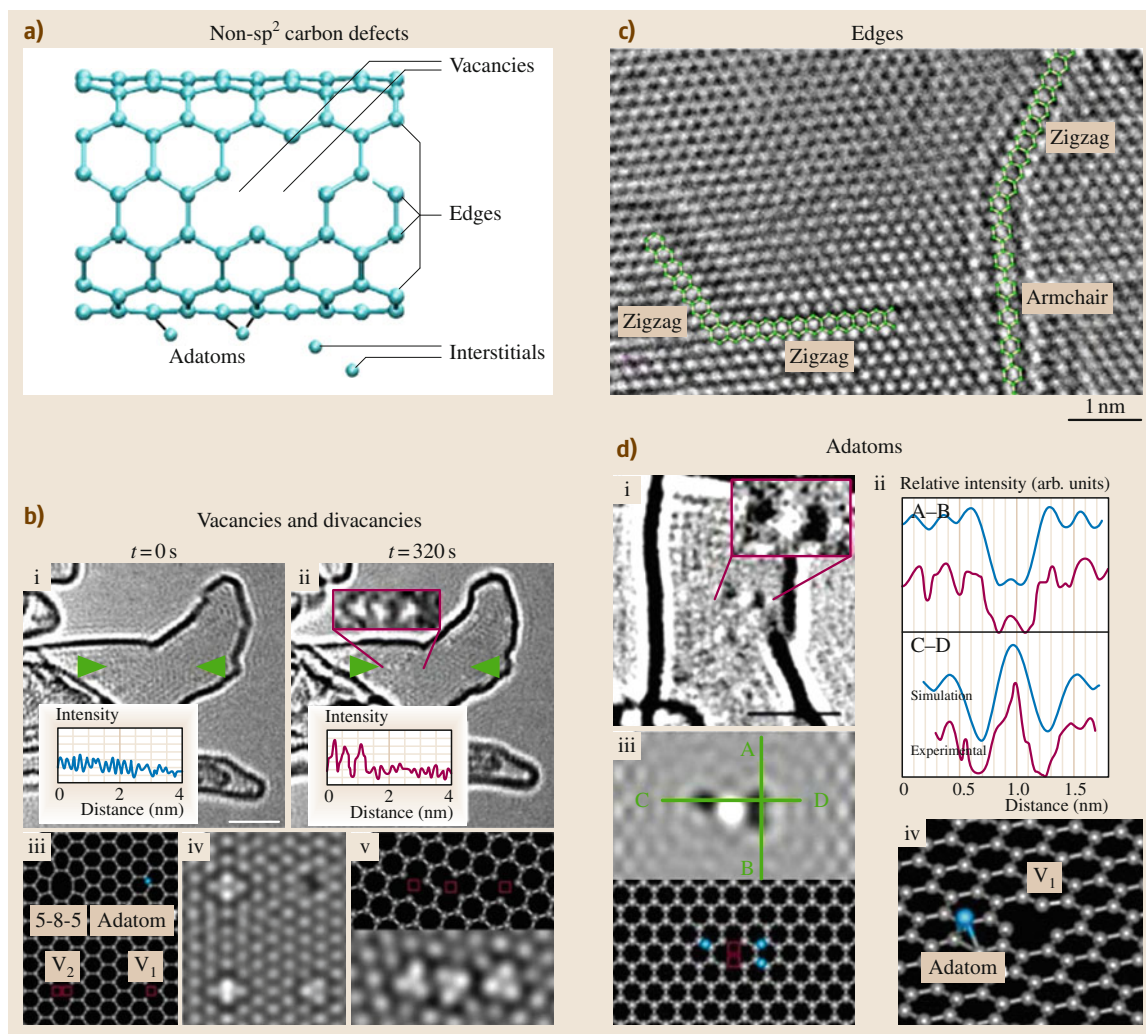

2. *Topological defects or bond rotations* occur on nanotube surfaces and do not result in significant changes in the overall curvature of the tube. In particular, these defects could be 5–7–7–5 pairs embedded in the hexagonal network (Fig. 6.7) or Thrower–Stone–Wales (TSW)-type defects [6.50, 51] that could be created by rotating a carbon–carbon bond by 90° within four neighboring hexagons, thus resulting in the transformation of two pentagons and two heptagons [6.52, 53].

Fig. 6.9 (a) Molecular model of the different types of non- sp^2 defects in graphene: vacancies interstitials, adatoms, edges, and interstitials. (b) Experimental images showing the creation of vacancies in graphitic materials (i, ii) and ii-inset, molecular models and HRTEM image simulations are also shown for clarity (iii–v); after Hashimoto et al. [6.54]. (c) HRTEM image of graphene edges exhibiting zigzag and armchair edges, obtained by applying Joule heating on individual graphene nanoribbons inside the HRTEM [6.55]; (di,dii) HRTEM image of adatoms on a graphitic surface (darker contrast spots); (diii,iv) HRTEM simulations and models of different configurations of adatoms on the surface of graphene that correspond to the experimental observations (after Hashimoto [6.54]) ►

It is noteworthy that the electronic and chemical properties of these 5–7 or 5–7–7–5 pairs (Fig. 6.7) are different from the structural defects, and their reactivity and detection need to be investigated theoretically and experimentally. Recently, Zettl and coworkers were able to observe directly 5–7 and TSW-type defects on isolated graphene surfaces using aberration-corrected transmission electron microscopy (Fig. 6.7); see also the movies in the supplementary material of [6.49].

3. *Narrow-diameter nanotubes or collapsed nanotubes* could be observed in large diameter nanotubes (Fig. 6.8a). Their chemical reactivity and electronic properties have not been investigated in detail. Narrow or highly curved nanotubes (usually < 1 nm diameter) would also be more reactive when compared with a flat graphene sheet (the π orbitals would be distorted in highly curved regions). A hybrid structure including a collapsed nanotube and narrow-diameter tubes (binocular-like) is depicted in Fig. 6.8b,c. At present, nanotube chemistry requires better understanding of these defects in order to induce and control strong (or weaker) covalent (or π – π) interactions with other molecules, atoms or clusters.

4. *Non- sp^2 carbon defects* are caused by the presence of highly reactive carbon atoms such as dangling bonds, carbon chains, interstitials (free atoms trapped between SWCNTs or between graphene sheets), edges (open nanotubes), adatoms, and vacancies (Fig. 6.9). These defects are usually observed by high-resolution transmission electron microscopy (HRTEM), when the adsorbed atoms on these reactive sites are removed by the electron beam energy.

6.3 Nanotube Chemical Functionalization

MWCNTs and SWCNTs have resulted in important discoveries in the area of chemistry and materials science over recent years. These nanoscale tubular structures possess tremendous strength [6.56] and extreme aspect ratio, and are excellent thermal and electrical conductors [6.57]. Carbon nanotubes promise to have a large number of potential applications, and some progress is being made towards commercial applications. However, it is apparent that chemical modification of SWCNTs and MWCNTs will be necessary to achieve some of these ap-

plications. An important issue is to improve their dispersion and compatibility either in water-based solutions for biological and medical applications [6.58], or in a polymer matrix to create polymer composites with enhanced electrical and mechanical properties [6.59–61].

6.3.1 Covalent Modification

Various covalent functionalization strategies have been reported:

1. Defect site creation, and functionalization from the defect sites [6.62]
2. Creation of carboxylic acids on the end caps of carbon nanotubes and subsequent derivatization from the acids [6.63, 64]
3. Covalent sidewall functionalization [6.56].

In particular, covalent functionalization of **SWCNTs** has been accomplished using three different approaches: thermally activated chemistry, electrochemical modification, and photochemical functionalization [6.65]. Although covalent functionalization methods have also been developed for **MWCNTs** [6.66], fewer investigations have been devoted to this type of nanotube.

Oxidation and Subsequent Nanotube Functionalization

There are many reports in literature related to successful chemistry with carbon nanotubes involving treatment under oxidizing conditions, such as sonication in mixtures of sulfuric and nitric acids, or

treatments with sulfuric acid/hydrogen peroxide [6.67, 68], potassium permanganate in acidic solution [6.69] or potassium dichromate/sulfuric acid. These processes also help to remove unwanted carbonaceous materials from raw nanotube samples. In addition, these processes can be used to shorten carbon nanotubes. Such shortening leaves carbon nanotubes with open ends decorated with an indeterminate number of oxygenated functionalities (Fig. 6.10) such as carboxylic acids, anhydrides, quinones, and esters. Such functionalities can also be introduced by treating carbon nanotubes with ozone [6.70–73]. The distribution of these functionalities has not been well characterized; they are presumed to exist primarily at the ends of nanotubes and at sites along the sidewalls, where increased curvature results in increased reactivity [6.74]. The concept of higher reactivity at defect sites such as pentagon–heptagon pairs called Thrower–Stone–Wales type defects, sp^3 -hybridized defects, and vacancies in the nanotube lattice, or sites of increased curvature (especially end caps and kinks), has been described in literature [6.75], as well as the increased reactiv-

Fig. 6.10 Schematic representation of the oxidation process in a carbon nanotube, and two possible routes of functionalization

ity of smaller-diameter SWCNTs [6.76]. Functional groups created in this manner (carboxylic acid, ketone, alcohol, ester groups, etc.) can be removed by heating the samples in a vacuum or inert atmosphere [primarily esters and quinones based on infrared (IR) absorption frequencies], thus leaving the nanotube walls almost intact. It is noteworthy that the presence of carboxylic acid functionalities in carbon nanotubes provides a large number of possibilities for achieving chemical modifications.

Fluorination

Fluorination is a process that involves addition of fluorine atoms onto the surface of carbon nanotubes, thus causing significant alteration of their properties [6.78]. A possible route involves treatment of CNTs with hydrazine, or alkyl-magnesium bromides or alkyl-lithium reagents to yield alkylated CNTs which are later fluorinated. Other fluorination processes have been reported via aryl diazonium salts, carbenes, nitrenes, organic radicals, etc. These fluorinated CNTs are now sold commercially [6.79]. Fluorinated CNTs result in significant changes in the spectroscopic properties [ultraviolet (UV)/Vis/near infrared (NIR) absorption and Raman scattering], thermogravimetric analysis (TGA), and enhanced solubility in organic solvents (2-propanol, 2-butanol, *n*-pentanol, *n*-hexanol, mixtures of acetone and water, etc.) [6.80]. Covalent functionalization such as fluorination appears to have strong effects on the electrical conductivity of functionalized materials, which greatly differs from that of pristine carbon nanotubes. It has been reported that the thermodynamic stability of fluorinated SWNTs decreases with tube diameter, meaning that the dissociation energy of the C–F bonds increases as the diameter decreases. C–F bonds were also found to be covalent (with bond length ranging from 1.41 to 1.45 Å). Fluorinated carbon nanotubes have found some applications in the fabrication of cathodes, electrochemical cells, etc., but further studies on different degrees of fluorination should be carried out. It is believed that it is possible to tune the electronic and chemical properties of nanotubes by synthesizing fluorinated tubes with different concentrations of F atoms on their surfaces and ends.

Aryl Diazonium Chemistry

Diazonium compounds are organic compounds whose functional group is represented as $R-N_2H^+X$, in which R could be any organic compound and X an inorganic or organic anion. The importance of these salts in carbon nanotube functionalization is that they can form an

Fig. 6.11 Scheme for functionalization of carbon nanotube with diazonium salts

aryl radical that can then efficiently react with the walls of carbon nanotubes. The chemical activity of aryl di-

Fig. 6.12a,b Schematic description of functionalization techniques: (a) cycloaddition of nitrenes and (b) nucleophilic carbene functionalization (after [6.77])

azonium salts with highly oriented pyrolytic graphite (HOPG) and other carbon surfaces has been demonstrated [6.62]. This reaction presumably occurs when the diazonium salt is added to the nanotube suspension. An electron is then injected into the diazo functionality, liberating N_2 and forming a reactive aryl radical, which immediately reacts with the carbon nanotube sidewalls as shown in Fig. 6.11 [6.81]. These methods can be very versatile, since aryl diazonium salts can bear a wide variety of substituents to decorate carbon nanotubes with different functionalization groups. This method could also be scaled up.

Carbenes and Nitrenes

Nitrenes ($R-N:$) are analogs of carbenes. These compounds are considered electrophile reagents which can add carbon-carbon double bonds. Nanotube functionalization with nitrenes proceeds by thermolysis of alkyl azidoformates (Fig. 6.12a). The same reaction mechanism is followed during functionalization of carbon nanotubes by carbenes. First, nucleophilic carbene is formed by deprotonation of imidizolinium cation, and second, one negative charge per attached moiety is transferred to the nanotube (Fig. 6.12b), thus obtaining functionalized carbon nanotubes [6.82, 83].

6.3.2 Functionalization of Carbon Nanotubes via $\pi-\pi$ Interactions

A great number of routes to noncovalent modification of carbon nanotubes have been reported. In this way, the

original tubular structure is preserved and the technique does not damage the surface of the CNTs. Noncovalent carbon nanotube functionalization strategies can be classified into two groups: (a) via $\pi-\pi$ interactions, or (b) by electrostatic interactions. In the following paragraphs both strategies are explained and many examples are given to illustrate them (Fig. 6.13).

Since nanotube covalent functionalization may significantly alter the robustness of the system as well as its optical, electrical, and thermal properties, noncovalent nanotube functionalization approaches should be exploited [6.84]. Functionalization via $\pi-\pi$ interactions relies on the interactions established between carbon nanotubes and nonpolar molecules when these molecules contain aromatic rings or $C=C$ bonds. These interactions could be very stable [6.85] and are caused by $\pi-\pi$ stacking. This stacking was originally proposed as an explanation for the attractive interaction existing between molecules containing π orbitals in the absence of spectroscopic evidence for highest occupied molecular orbital (HOMO)–lowest unoccupied molecular orbital (LUMO) interactions [6.77]. A $\pi-\pi$ interaction is an electrostatic interaction in which the offset and/or orientation of the π orbitals on opposing molecules maximize the $\sigma-\pi$ attractive interactions while minimizing the opposing $\pi-\pi$ repulsive interactions. Such interactions with CNTs can be surprisingly strong, depending on the molecules, and even capable of withstanding temperatures $> 400^\circ C$ [6.86]. Since these interactions do not cause significant effects on the electrical and mechanical properties of

CNTs, these functionalization methods have attracted considerable attention of numerous scientists in order to obtain novel functional carbon nanomaterials. Table 6.1 presents some examples of this kind of functionalization.

A number of routes to noncovalent modification of carbon nanotubes have been reported, including polymer wrapping and adsorption [6.87, 88, 103], adsorption of amines [6.104] and molecules with large π -systems [6.89], complexation with organometallic compounds [6.105], and radiofrequency glow-discharge plasma modification [6.106]. Table 6.1 presents several examples related to the type of functionalization. This strategy can be applied not only to SWCNTs but also to MWCNTs and possibly graphene. From the examples described in Table 6.1, it is worth mentioning that the main objective of functionalization in most cases is to enhance the solubilization of the carbon nanotubes in polar solvents for further applications. These surface moieties act as effective anchoring sites on the

CNT surface and can be used to adsorb other functional molecules, clusters or nanoparticles.

6.3.3 Electrostatic Functionalization of Carbon Nanotubes

To functionalize CNTs electrostatically, first it is necessary to modify the nanotube surface to create some active sites. These active sites can be obtained by covalent functionalization or molecular adsorption via $\pi-\pi$ interactions. This first functionalization step will then allow electrostatic interactions with different molecules, thus enhancing its adsorption on the surface of carbon nanotubes. For example, CNTs functionalized with oxygen functional groups, mainly carboxylic groups [6.107], could then be decorated with different molecules via electrostatic functionalization. In Table 6.2, various examples of different types of electrostatic functionalization routes are presented to illustrate the wide spectrum of possibilities to synthe-

size different functional materials for different specific applications.

It is noteworthy that electrostatic functionalization of carbon nanotubes is normally carried out by synthetic or natural polyelectrolytes such as polyethyleneimine (PEI) [6.110, 117], polystyrene sulfonate sodium salt (NaPSS) [6.117], deoxyribonucleic acid (DNA), different proteins [6.111, 112, 118], etc. This is due to the fact that these molecules have the possibility to have high charge density, thus allowing an increase of anchoring points on the CNT surface. Due to the possibility of using polyelectrolytes of natural origin,

this functionalization is ideal to produce biocompatible CNTs for further biomedical applications [6.112, 118]. Electrostatic functionalization also enables decoration of CNTs with different metallic nanoparticles or functional molecules for use in the fabrication of efficient sensors and even catalysts [6.111, 113, 115, 120].

Functionalization of carbon nanotubes while preserving their structural integrity opens a wide range of novel applications, especially if doped carbon nanotubes are used. This kind of soft physical chemistry helps to preserve carbon nanotube properties, thus enhancing and expanding their fields of application.

6.4 Properties of Modified Carbon Nanotubes

This section shows that CNTs are sensitive to any modification of their crystalline lattice. Changes in their atomic structure could result in different electrical, mechanical, and chemical properties. Even if they do not exhibit any covalent modification, their interaction with foreign molecules may also affect the way they behave.

6.4.1 Electrical Properties of Modified Tubes

Nitrogen-doped carbon nanotubes (CN_x) may have higher conductivity than carbon nanotubes, originating from the isolated pair of electrons introduced by the substitutional doping of nitrogen which is conjugated with π orbitals [6.121, 122]. This π interaction is capable of converting a semiconducting (zigzag) carbon nanotube to metallic by introducing electronic states at or close to the Fermi level. Experimental measurements have shown that nitrogen-doped SWCNTs require less energy to excite carriers into the conduction band [6.123]. Mats of CN_x could exhibit electrical conductivities in the range of ca. 200–450 $\Omega^{-1} \text{ cm}^{-1}$. In addition, the conductivity could be tailored according to the doping concentration within the CNTs (Fig. 6.14a,b) [6.124]. These N-doped CNTs could exhibit larger third-order susceptibility and better ultrafast saturable absorption of visible light when compared with undoped CNTs. This phenomenon is caused by the high density of π electrons in the system.

Doping carbon nanotubes with boron introduces hole-type charge carriers. Although these defects will increase the electron scattering density, they could lead to enhanced conductivity values by lowering the resistivity by an order of magnitude (7.4×10^{-7} – $7.7 \times 10^{-6} \Omega \text{ m}$) when compared with pure carbon MWCNTs (5.33×10^{-6} – $1.9 \times 10^{-5} \Omega \text{ m}$) (Fig. 6.14c) [6.125–128]. These B-doped CNTs possess a low temperature dependence of resistivity; it is thought that close to 0 K the total number of conduction channels increased with the number of conduction carriers (hole carriers induced by boron doping) [6.129]. The optical absorption spectra of the boron-doped SWCNTs indicate the presence of a new peak at ca. 0.4 eV, which is assigned to the valence band of a new acceptor band caused in-plane doping of boron within the SWCNTs [6.130].

When intercalating iodine in SWCNT mats, the resistance at 300 K may be reduced by a factor of ≈ 40 (compared with the pristine sample). Here, iodine atoms

increase the concentration of mobile holes in the π -electron bands of the nanotubes (Fig. 6.14d) [6.131]. In addition, iodine-doped DWCNT cables have shown lower resistivity values ($1.5 \times 10^{-7} \Omega \text{ m}$) compared with their undoped counterparts ($5 \times 10^{-7} \Omega \text{ m}$). In addition, the doped systems have lower specific conductivity ($1.96 \times 10^4 \text{ S m}^2/\text{kg}$) when compared with aluminum or copper, and similar current capacity to copper (104 – 105 A/cm^2) [6.132]. The conductivity of fluorinated SWCNTs has also been studied, and the results show that it differs dramatically from that of pristine SWCNTs; a sample of pristine SWCNTs was reported to have resistance of 10 – 15Ω , whereas fluorinated SWCNTs displayed resistance $> 20 \text{ M}\Omega$ [6.78].

6.4.2 Electrochemistry of Modified Nanotubes

Due to the excellent electronic properties of carbon nanotubes and their reactivity after modification, their electrochemical properties and applications have been studied. These modifications may be classified into redox enzyme interactions, metal nanoparticle anchoring, doping, conductive polymer doping, covalent modification, and intercalation.

Redox-Enzyme-Modified Carbon Nanotubes

High-surface-area carbon materials have long been used as a conductive matrix for redox enzyme immobilization to enable use of this carbon-enzyme nanocomposite as a transducer in electrochemical sensors. The small diameter of SWCNTs means that this material is capable of being in close contact with the active site of several oxidoreductases, thus exhibiting enhanced electron transfer when compared with flat carbon surfaces such as HOPG and carbon paste electrodes. Among different enzymes, laccases, peroxidases, glucose oxidase, alcohol oxidase, cholesterol oxidase [6.133], and many others have been reported to interact well with CNTs. Recently, the possibility of using carbon nanotube composites with redox enzymes not only in sensors but also in fuel cells has attracted great attention. Figure 6.15a shows a potential biofuel cell configuration using modified carbon nanotube electrodes. By using redox mediators, both the anode and cathode could be constructed with carbon nanotubes and redox enzymes. Over recent years, direct electron transfer between redox enzymes and carbon electrodes has been studied. Direct electron

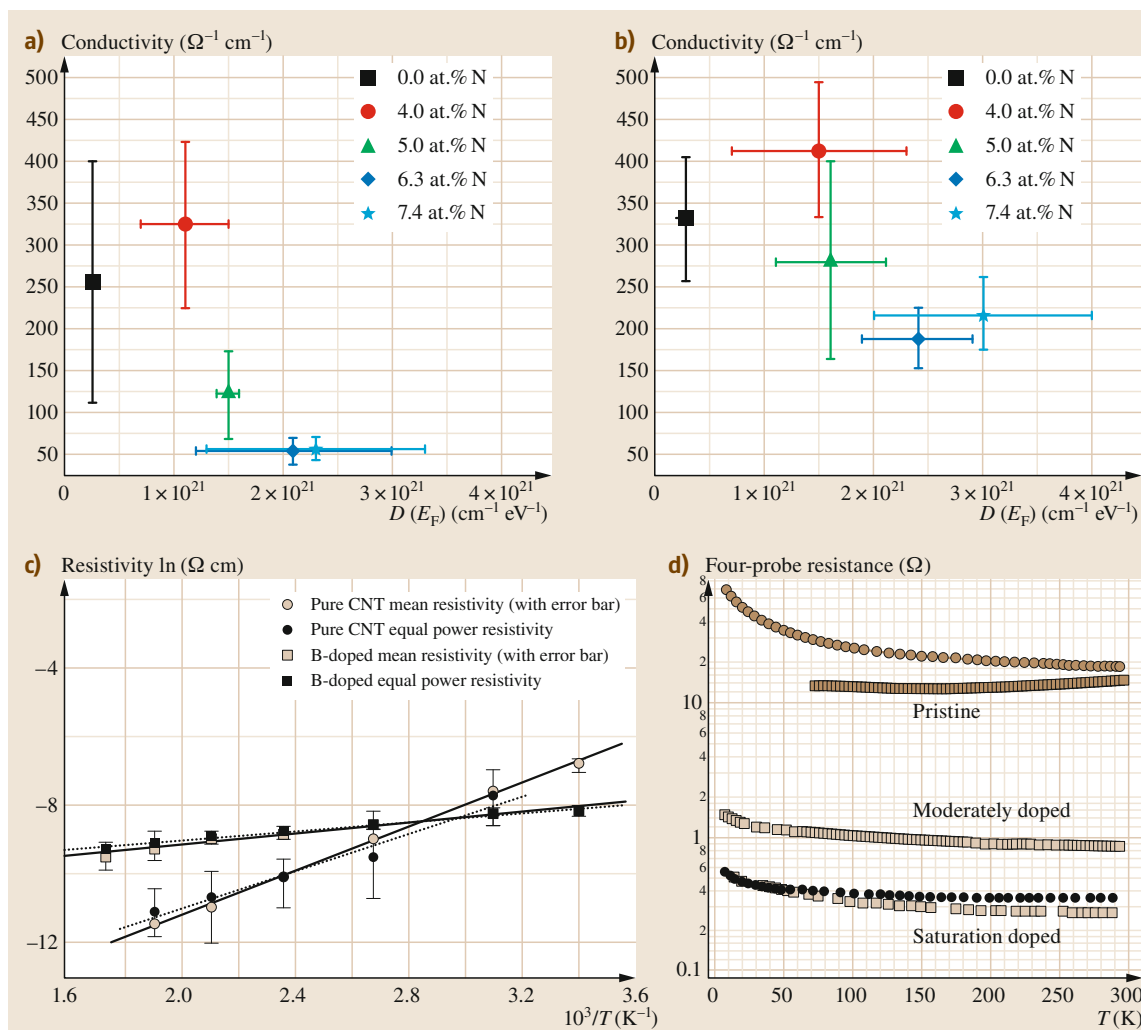

Fig. 6.14a–d Plots of conductivity versus density of states, $D(E_F)$, at the Fermi level of N-doped CNT mats that are (a) acid treated and (b) pristine (after [6.124]). (c) Resistivity versus temperature of pure and boron-doped MWCNTs (after [6.128]) and (d) resistivity versus temperature of pristine and iodine-doped SWCNTs (after [6.131])

transfer should result in higher available potential, but the high charge-transfer resistance limits the power available of these devices. Rivas and Rubianes [6.134] reported direct electron transfer from glucose oxidase to CNTs, and its application to glucose biosensors. These authors found excellent response of glucose oxidase with low interference from compounds such as uric acid and acetaminophen. The results indicate that nanotubes could also improve the specificity of the electrochemical oxidation of some compounds. Other authors have demonstrated that cytochrome C peroxidase

could be immobilized in polyaniline (PANI)/MWCNT electrodes by electrochemical oxidation followed by adsorption [6.135]. It was shown that these composite electrodes exhibit direct electron transfer as well as bioelectrocatalytic activity towards hydrogen peroxide. Subsequently, Liu et al. managed to immobilize glucose oxidase on PANI- Fe_3O_4 -CNT electrodes. The modification of these nanotubes is rather complex because it involves an electroactive biomolecule, a conductive polymer, and a metal oxide. However, the electrochemical response towards glucose oxidation was very

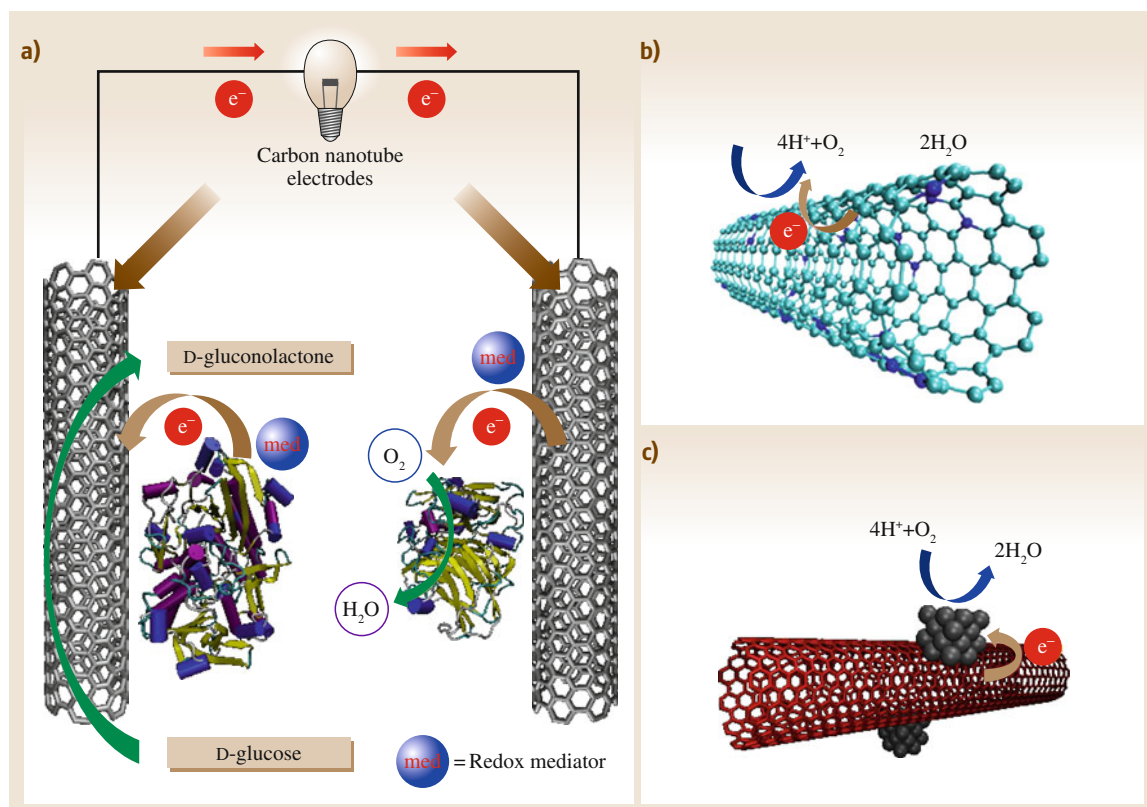

Fig. 6.15 (a) Typical biofuel cell configuration using carbon nanotube electrodes modified with redox enzymes. On the left, a carbon nanotube modified with glucose oxidase catalyzes the oxidation of glucose to yield gluconolactone. On the right, a SWCNT modified with laccase catalyzes the reduction of oxygen to water. (b) Scheme for oxygen reduction on the surface of a nitrogen-doped CNT. The doping sites work as electrocatalytically active sites that promote oxygen reduction. (c) CNT decorated with Pt nanoparticles. The metal nanoparticle has electrocatalytically active surfaces that promote reduction of oxygen to water. Electron transfer is mediated through the metal nanoparticle

efficient, and the electrode material displayed good dispersibility in water and superparamagnetic properties, an important issue from the biomedical point of view. Chen and Lu [6.136] assembled hemoglobin using a mixture of polyelectrolytes and a surfactant. The electrochemical response was studied by cyclic voltammetry, and the assembled material showed enhanced reduction of hydrogen peroxide. Table 6.3 presents some of the redox enzyme–carbon nanotube assembly systems that have been studied.

Metal Nanoparticle Modified Carbon Nanotubes

Carbon nanotubes are electrically conductive nanomaterials, with relatively high surface area and robust mechanical properties. For these reasons, carbon

nanotubes have potential applications as an electrode support for electrocatalytically active metal nanoparticles (NPs). Various metal nanoparticles could catalyze the electrochemical oxidation/reduction of chemical compounds and efficiently transfer charge to electrically conductive supports. Electrodes made of carbon nanotubes and metal nanoparticles might find direct application in fuel cell technologies (Fig. 6.15c). In this context, Che et al. [6.137] used graphitic carbon nanotubes prepared using a template method to support Pt/Ru nanoparticles that showed electrocatalytic activity towards O_2 reduction and methanol oxidation. Later, MWCNTs prepared by chemical vapor deposition (CVD) were decorated with platinum nanoparticles by Liu et al. [6.138]. The Pt-coated nanotubes showed a typical cyclic voltammetry reduction peak for oxy-

MWCNT	Laccase	Ascorbate/O ₂ biofuel cell developed	[6.158]

gen reduction, and the Pt–MWCNT composites were evaluated in real fuel cells, showing good performance with high exchange current density and low DC resistance. Indeed, compared with carbon black, CNTs exhibit higher electrical conductivities due to their high aspect ratio and degree of crystallinity. To increase the electrode efficiency, MWCNTs grown on carbon fibers were used as support for Pt nanoparticles, and their electrochemical behavior was characterized by cyclic voltammetry. These reports opened a field related to the use of CNTs in fuel cell technologies. Table 6.4 presents some publications related to the decoration of carbon nanotubes with metal nanoparticles and their use for electrocatalytic applications.

Doped Carbon Nanotubes

Increase of the nitrogen content in CNTs also increases their capacitance, because the number of active sites for electron transfer increases (Fig. 6.15b) [6.124]. It has been suggested that the pyridinic sites may act as reducing points within CNTs [6.159]. Nitrogen-doped carbon nanotubes exhibit enhanced catalytic activity for oxygen reduction in fuel cells; this process follows a four-electron pathway. The advantage of N-doped CNTs is that they have exceptional resistance to CO poisoning and selectivity, when compared with Pt-based systems [6.160, 161]. Doped nanotubes have also shown higher electron transfer to redox enzymes when compared with pure CNTs. Nitrogen- [6.155] and

boron-doped [6.162] CNTs have been assembled with glucose oxidase; here, better sensitivity and increased linear response were found, making these nanotubes excellent candidates for direct electrochemistry with redox enzymes.

Conductive Polymer-Doped Nanotubes

Not only conducting polymers but also hybrid coatings of conductive polymer–inorganic materials have been employed to modify the electrochemical response of CNTs; for instance, phosphomolybdate/polypyrrole (PPy) and phosphomolybdate/poly(3,4-ethylenedioxythiophene) (PEDOT) coatings have been deposited on CNTs by adsorption followed by electrochemical oxidation. The process was repeated several times to achieve a layered structure. The resulting composite re-

vealed high electrocatalytic activity towards reduction of bromate ion. Polyaniline (PANI)-coated MWCNTs have been prepared by electrochemical oxidation in the presence of amine-modified MWCNTs [6.187]. This composite showed good electrochemical response in amperometric detection of celecoxib, a nonsteroidal anti-inflammatory drug. This improved response is attributed to both an increase of electrochemical available area and promoted adsorption of the drug on the polyaniline-modified electrode. By simple mixing of a colloidal dispersion of PANI nanofibers and water-dispersable MWCNTs, composite electrodes were prepared by Yang et al. [6.188]; the composite exhibits great capability for detecting DNA hybridization. When using redox probes it has been shown that the composite has improved electron transfer ability when compared

with PANI or MWCNT alone, and the redox activity of PANI plays a key role in the regeneration and stability of the biosensor. *Hu* et al. have also examined the electrochemical response of PANI/MWCNT–poly(sodium 4-styrenesulfonate) (PSS) composite electrodes, prepared by layer-by-layer self-assembly [6.189]. These authors showed that anionic MWCNT–PSS could dope cationic polyaniline, and that the technique could be used to construct electrodes in a reliable way. Composite electrodes of DWCNT/PEDOT:PSS were studied by *Kalbáč* et al. [6.190], and they found that, after mixing DWCNTs with the conductive polymer, the Raman bands of the carbon nanotube shifted whereas those of the polymer remained intact. By using in situ Raman spectroelectrochemistry, it was shown that the CNTs change their electronic conformation as a function of the potential charge. It is also noteworthy that electrochemical synthesis of PEDOT in the presence of MWCNTs results in composite electrodes with lower charge transfer impedance, lower internal resistance, and superior capacitive response. These improved electrical properties result in faster response and better coloration efficiency in electrochromic devices.

Covalently Modified Nanotubes

Modification of CNTs with either electroactive or non-electroactive molecules by covalent bonding results in alteration of their electrochemical response. Recently, MWCNTs were modified by covalent bonding with neutral red [6.191], a nitrogen-containing polycyclic compound which can behave as a redox mediator. These nanotubes showed better electrochemical transfer to glucose oxidase and were employed to construct

biosensors. The covalent bonding between the redox mediator and the MWCNTs improves its long-term stability. In a similar approach, MWCNTs were modified with thionine in order to increase its electrocatalytic activity towards hydrogen peroxide reduction [6.192]. Due to the covalent bonding, the electrochemical response decreased by less than 5% over 150 days of use. Sidewall-functionalized aminated MWCNTs were also immobilized on silicon surfaces via a carbodiimide reaction, and the electrochemical properties were evaluated by scanning electrochemical microscopy, with and without redox mediators. In this case, the MWCNTs enabled efficient electrical communication between the silicon surface and the redox probe in solution [6.179].

Electrochemical Intercalation of Nanotubes

Lithium ions have been intercalated between MWCNTs, exhibiting a reversible capacity that is sensitive to the processing conditions; the obtained values are between 100 and 400 mA h/g [6.193]. In addition, by intercalating Li within the hollow cores of SWCNTs, it is possible to obtain a high reversible capacity of 1000 mA h/g [6.194], the observed saturation Li/C ratio for shortened SWCNTs being ca. $\text{LiC}_{3.35}$ [6.194, 195]. Here, Li ions may be located on the outer surfaces of the CNT; however, the results are enhanced when the carbon nanotubes are shortened, leaving open tips available for intercalation of Li ions within the cores, since Li ions display a diameter of 0.7 Å and SWCNTs exhibit larger diameters of 1.3–1.6 nm. Li ions could diffuse through defect sites created by oxidation into the cores of the CNTs, thus causing a lower irreversible capacity due to the difficulty for Li ions to deintercalate [6.194, 196].

6.5 Characterization of Modified Carbon Nanotubes

Once carbon nanotubes have been modified, it is important to monitor the resulting changes. For this reason, the most commonly used techniques used to characterize CNTs are discussed in this section. These techniques mainly consist of transmission electron microscopy (TEM), atomic force microscopy (AFM), scanning transmission microscopy (STM), electron energy loss spectroscopy (EELS), x-ray photoelectron spectroscopy (XPS), Raman spectroscopy, and thermogravimetric analysis (TGA).

6.5.1 Transmission Electron Microscopy

This technique enables direct observation of the walls of the carbon nanotube, capable of showing how crystalline or defective they are. This can be observed by the straightness of the walls, as the presence of defects in the carbon nanotube introduces variations in the local curvature within the nanotube lattice; for example, nitrogen-doped MWCNTs tend to create compartments within the hollow cores, resembling

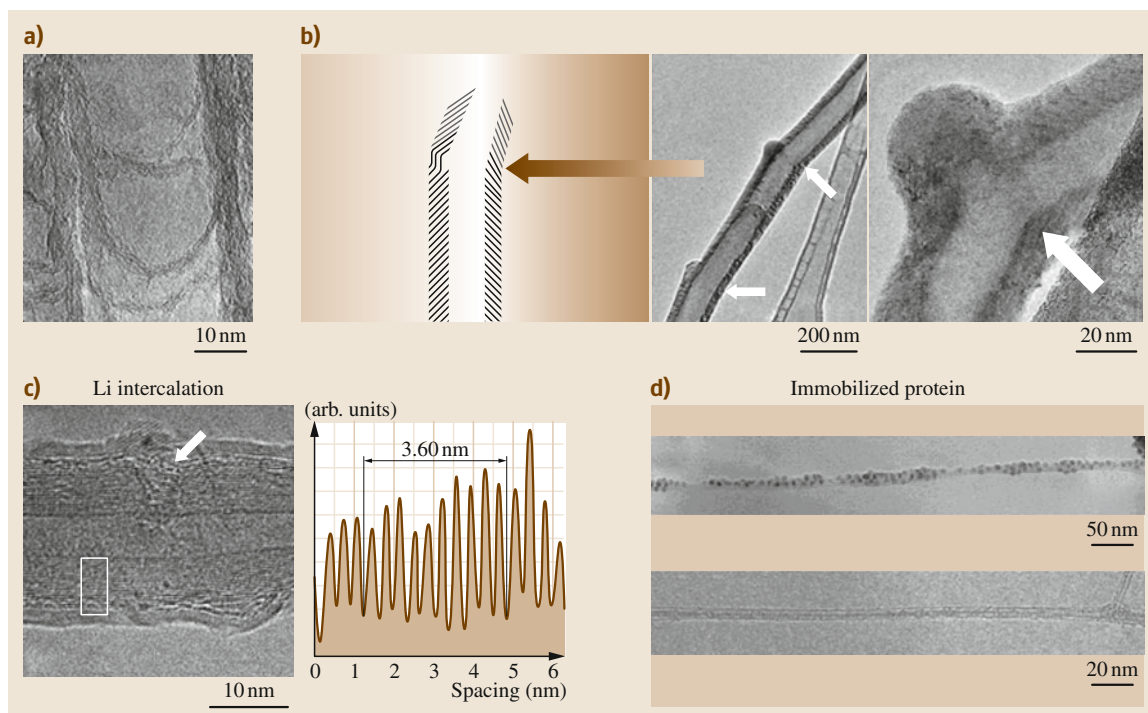

Fig. 6.16a–d TEM images of: (a) nitrogen-doped CNT with internal compartments resembling a bamboo-type morphology (after [6.122]); (b) sulfur-doped MWCNT with an extruding kink (after [6.197]); (c) effect of Li intercalation in a MWCNT, showing an increase in the interlayer spacing within the nanotube walls (after [6.198]); and (d) immobilized protein on the surface of a SWCNT (after [6.89])

a *bamboo-like* morphology (Fig. 6.16a) [6.122]. In addition, sulfur atoms have been reported to cause deformation of the tubular layers and the presence of branches (Fig. 6.16b) [6.197]. It is also possible to observe an increase in the interlayer spacings within the concentric walls of a MWCNT caused by alkali-metal intercalation. In this case, Li intercalation exhibits an interlayer spacing increase from 3.4 to 3.6 Å (Fig. 6.16c) [6.198].

TEM can also allow visualization of macromolecules such as polymers and proteins on the surface of carbon nanotubes. In this context, metal-containing proteins such as ferritin and streptavidin–Au conjugates have been observed as dark spots corresponding to the nanoparticles that are contained within the proteins (Fig. 6.16d) [6.89]. Regarding polymers, it is possible to visualize the wetting of the carbon nanotube walls with an amorphous-like polymer layer [6.199, 200].

6.5.2 Atomic Force Microscopy and Scanning Transmission Microscopy

AFM allows visualization of the morphology or phase changes within the surface of a sample. In this technique, a sharp tip approaches the desired surface and could be in full contact or tapping at a specific frequency. This tool has been used to visualize anchoring of biomolecules such as proteins and DNA onto carbon nanotubes. Proteins such as ferritin and streptavidin–Au conjugates appear as clusters under AFM [6.89]. DNA wrapped around MWCNTs could be observed as thin strands on the surface of the tube, where the nanotubes exhibit a nonsmooth surface due to the wrapping of DNA strands (Fig. 6.17a,b) [6.201].

Scanning transmission microscopy (STM) measures the electric potential differences across the surface of the sample and has been used to identify atomic de-

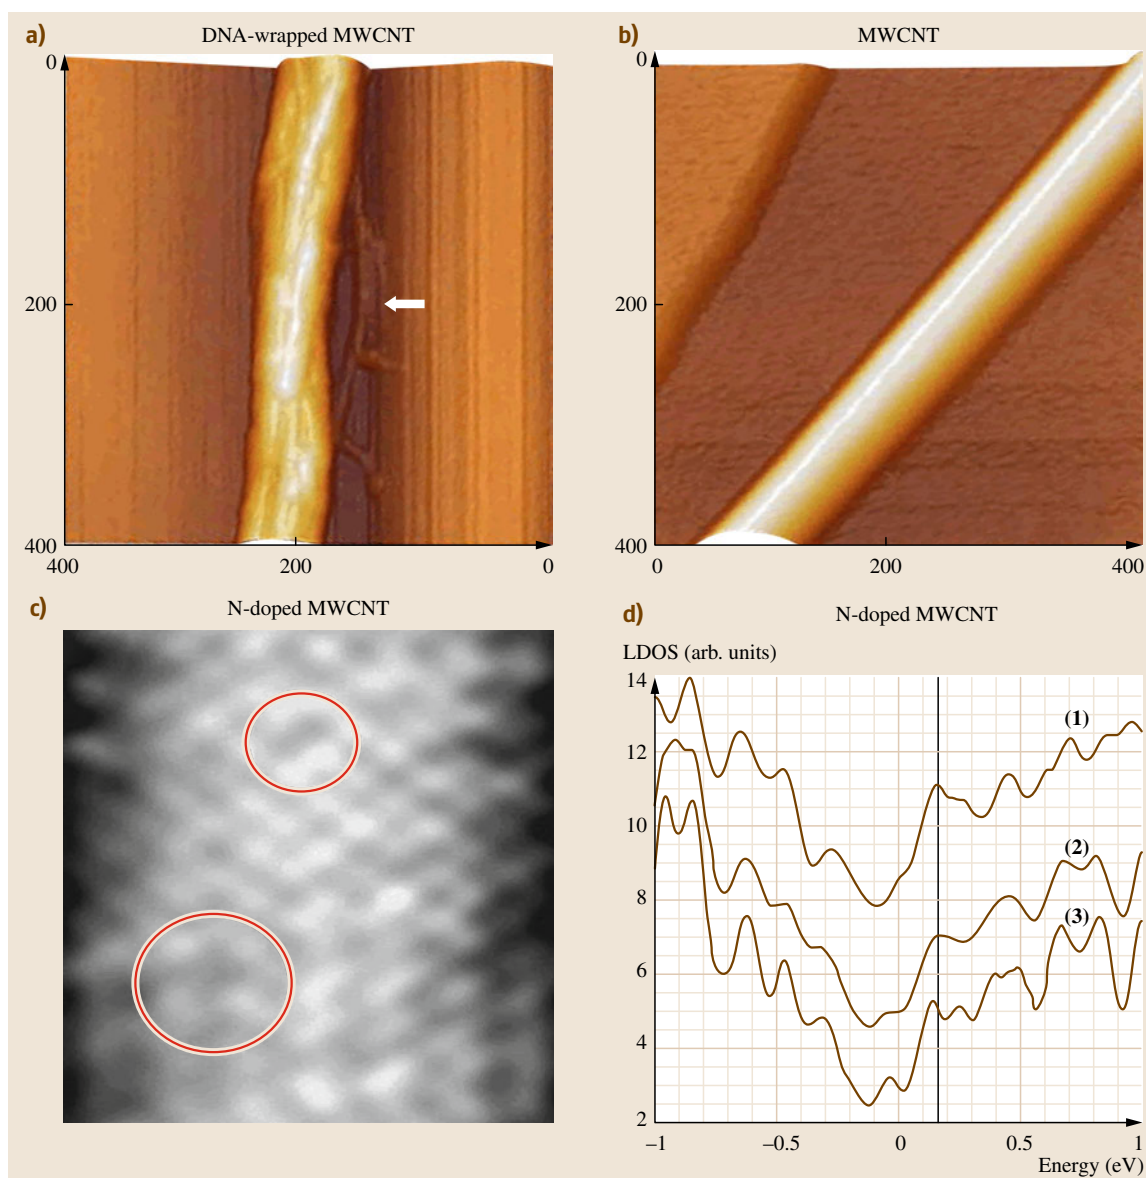

Fig. 6.17a–d Tapping-mode AFM images of (a) DNA strands wrapping a MWCNT and (b) a pure MWCNT (after [6.201]). (c) STM image of vacancies in a N-doped MWCNT caused by pyridine-like sites, and (d) scanning tunneling spectra taken at different sites of a nitrogen-doped MWCNT showing peaks located at ca. 0.18 eV in the conduction band (vertical line; after [6.122])

fects in carbon nanotubes. In particular, it has been used for nitrogen-doped CNT, where vacancies corresponding to pyridinic-type nitrogen atoms have been identified (Fig. 6.17c) [6.121]. When using the spectroscopy mode (STS), this technique can also provide

information related to the local density of states (LDOS) near the Fermi level. The technique has been used for nitrogen- and boron-doped CNTs, which exhibit characteristic spectra when compared to their undoped counterparts. Nitrogen (Fig. 6.17d) and boron

atoms result in donor and acceptor states, respectively [6.121, 202].

6.5.3 Electron Energy Loss Spectroscopy (EELS)

When a ray of fast electrons is aimed at a sample and these electrons are scattered, some may suffer inelastic scattering and be randomly deflected. The amount

of energy lost during the excitation of an electron from the inner electronic shell of an atom can then be determined. It is noteworthy that each element exhibits a unique energy loss for this type of inelastic interaction. EELS can therefore provide information related to the elemental composition of modified nanotubes; for example, boron- and nitrogen-doped CNTs have been analyzed by EELS [6.130, 205]. When a SWCNT is doped with boron near the C1s $\rightarrow \pi^*$ resonance lo-

cated at ca. 284 eV, the B1s ionization edge (π^*) can be observed at ca. 192 eV, showing that the B atoms are incorporated into the lattice [6.130]. For nitrogen-doped systems, the N-*K* edge shows the presence of trivalent nitrogen (401–403 eV) and pyridine-type sites (\approx 399 eV) [6.205]. EELS has also been used to observe covalent (\approx 685 eV) and ionic (\approx 690 eV) bonding in fluorinated MWCNTs (Fig. 6.18a) [6.203]. In addition, EELS has been used to study heterodoped nanotubes such as phosphorus-nitrogen (PN)-doped MWCNTs (Fig. 6.18b). Here, the presence of phosphorus atoms was confirmed by the ionization edge located at ca. 130 eV [6.204]. Furthermore, EELS has been used to determine whether alkali metals intercalated in MWCNTs and SWCNT bundles, calculated by the ratio of the spectral intensity of $I_{\text{alkali}}/I_{\text{C}}$ (alkali/carbon) [6.206, 207].

EELS in conjunction with TEM has been used to elucidate the elemental distribution in carbon nanotubes; for example, the following metal compounds encapsulated inside nanotubes have been detected: Fe₃P [6.204], Fe₃C, and FeO_x [6.226]. For nonmetallic elements it has been used for CNTs doped with fluorine [6.203] and nitrogen [6.211], and PN heterodoping (Fig. 6.18c,d) [6.204]. This technique has also been used for mapping sulfur in thiol group functionalization [6.227].

6.5.4 X-Ray Photoelectron Spectroscopy

X-ray photoelectron spectroscopy (XPS) consists of irradiating samples with a focused x-ray beam. The change in kinetic energy of the photoemitted electrons from the top surface of the sample (ca. 10–100 Å in depth) can be recorded using an energy analyzer. XPS is able to measure the elemental composition, chemical states, and electronic states of the elements present in the samples. This tool is capable of showing the elements and the types of bonds that are present in pristine or modified CNTs. Using this technique, one can determine the degree of crystallinity of CNT samples by studying the sp² C=C (284.3 eV) bonding; the less sp³ C–C (285.2 eV) bonds in the sample, the higher the degree of crystallinity of the CNTs [6.208–212]. Using this technique, it is also possible to identify C–N bonds by analyzing the C1s signal for C–N (2863 eV) and C=N (285.6 eV) [6.213]. From the N1s signal it is possible to determine substitutional (400.5 eV), pyridine-like (398.5 eV), and quaternary (401.2 eV) nitrogen, as well as nitrogen oxide (405 eV) [6.159, 214, 220–222, 224,

Table 6.5 Reported bonds within modified carbon nanotubes measured by x-ray photoelectron spectroscopy

F	O–COO	534.4	[6.215]
	Semiionic	686.2	[6.218, 219]
	Covalent	688.7	[6.218, 219]

225]. When carbon nanotubes are fluorinated, they exhibit fluorine peaks corresponding to semi-ionic (6862 eV) and covalent (688.7 eV) C–F bonds [6.101, 219, 228], and the C1s signal shows a variety of C–F (291.2 eV), C–F₂ (292.9 eV), and C–F₃ (294.6 eV) bonds [6.219]. When carbon nanotubes are oxidized, the presence of several C–O bonds may be monitored in the C1s region: C–O (286.5 eV), C=O (2873 eV), –COO (288.8 eV), O–C=O (288.5 eV), and O–COO (290.3 eV). Similarly, by analyzing the O1s signal, one can identify O=C (531.7 eV), O–C (533.3 eV), and O–COO (534.4 eV) functional groups [6.208–210, 212, 215–217]. In addition, from survey spectra it is possible to obtain the elemental concentration present in the entire sample [6.159, 214, 223, 229]. Table 6.5 summarizes the binding energies of different elements that have been reported in literature for different types of modified CNTs.

6.5.5 Raman Spectroscopy

Raman scattering consists of inelastic scattering in which:

1. An electron is excited so that it *jumps* from the valence band to the conduction band by adsorbing a photon
2. The excited electron may suffer scattering from the emission or absorption of phonons, and
3. A photon can then be emitted due to the relaxation of an electron back to the valence band.

Some characteristic Raman signals have been ascribed to **SWCNTs** and **MWCNTs**. In particular, the radial breathing mode (**RBM**) which is caused by a radial vibration mode ($100\text{--}500\text{ cm}^{-1}$) is used to determine the nanotube diameter of **SWCNTs**. The G-band corresponds to tangential vibrations and is located at ca. $1500\text{--}1605\text{ cm}^{-1}$. This band is related to the degree of crystallinity of graphite-like materials. The D-band arises from disorder present within the carbon hexagonal lattice; this peak is located at ca. $1250\text{--}1350\text{ cm}^{-1}$. The G'-band (D-band overtone) (ca. $250\text{--}2900\text{ cm}^{-1}$) arises from a two-phonon, intervalley second-order Raman scattering process and may be observed from defect-free sp^2 -hybridized carbons. The D-band and G'-band are very sensitive to the laser excitation energy [6.230, 231].

Introduction of disorder into nanotubes will reduce their crystal symmetry; here, phonon modes at the Γ point can be allowed, and phonon modes within the Brillouin zone may participate in a double resonance process, all of which may cause broadening of the Raman peaks [6.232, 233]. In particular, for carbon nanotubes containing a large concentration of defects, the scattering cross section might increase, as well as the double-resonant Raman modes in the first-order spectra.

The description of double resonance establishes that the G-band phonon wavevectors are closer to the Γ point than those of the D-band [6.234]. With low defect concentration the phonon wavevectors are in the range of $0.1\text{--}0.3\pi/a_0$ (where a_0 is the length of the graphene lattice vectors), independent of the nanotube chirality. However, at high defect concentrations, these phonon wavevectors are large when compared with those observed at the Γ point. Therefore, when the defect concentration is large enough, the separation distance between defects becomes similar to the D-band phonons.

The G'-band [also known as the two-dimensional (2-D) band by some authors] is highly sensitive to modifications in sp^2 -hybridized carbon structures, including nanotube diameter and structural changes induced by doping [6.235, 236]. In particular, it has been ob-

served that a lower-frequency peak next to the G'-band arises due to the presence of defects in **SWCNTs**, and depending on the band shifts, one can determine whether the defect introduces acceptors or donors in **SWCNT** samples (Fig. 6.19a) [6.236, 237]. This low-frequency G'-band has been used to study phosphorus- and nitrogen-doped **SWCNTs**. This mode is known as G'_D (where "D" stands for defect), and the frequency difference between the undoped G', called G'_P (where "P" stands for pristine) and the G'_D band ($\omega_{G'_P} - \omega_{G'_D}$) is negative for p-doped (electron acceptor atoms) **SWCNTs** but positive for n-doped (electron donor atoms) **SWCNTs** [6.237, 238]. In addition, the frequency splitting $\omega_{G'_P} - \omega_{G'_D}$ exhibits a certain range of values depending upon the dopant; $\approx 31\text{--}33\text{ cm}^{-1}$ corresponds to phosphorus, $\approx 35\text{--}40\text{ cm}^{-1}$ corresponds to nitrogen, and $\approx 41\text{--}45\text{ cm}^{-1}$ corresponds to silicon (Fig. 6.19b). Furthermore, the $I_{G'_D}/I_{G'_P}$ ratio has been used to study **SWCNTs** doped with nitrogen, phosphorus, and silicon, and the results show that this ratio increases when the amount of dopant per carbon atom increases within the structure (Fig. 6.19c) [6.239].

Various authors use the ratio of the relative intensities of the D-band and G-band (I_D/I_G) to obtain the degree of crystallinity of samples. Higher ratios are related to higher content of defects; for example, this relationship has been widely used to study the air and acid oxidation process of **MWCNTs**, showing that I_D/I_G increases with higher oxidation temperatures and that this ratio also increases when the acid treatment reaction time is longer. In this way, it was determined that the acid treatment is a strong nanotube oxidizer [6.240]. Other comparisons using different acid solutions to oxidize **MWCNTs** revealed that $\text{NH}_4\text{OH}/\text{H}_2\text{O}_2$ is a very strong agent [6.216]. For nitrogen-doped **MWCNTs**, the I_D/I_G ratio increases when the content of substitutional and pyridinic nitrogen increases [6.224]. A similar increase has also been observed when increasing the amount of dopants in phosphorus-doped **SWCNTs** [6.238], nitrogen-doped **MWCNTs** (Fig. 6.19d) [6.123, 234], nitrogen-doped **DWCNTs** [6.241], and boron-doped **MWCNTs** [6.127], and in fluorination of **SWCNTs** [6.237] and dichlorocarbene functionalization of **SWCNTs** (Fig. 6.19e) [6.242]. This ratio has also been used to monitor the anchorage of Pt nanoparticles onto oxidized **MWCNTs**, revealing that the ratio decreases with this anchorage of **NPs** since these particles prefer to adsorb at defective sites [6.243]. In addition, the ratio between the D-band and G'-band ($I_D/I_{G'}$) has been used to study the degree of functionalization of **SWCNTs** [6.244, 245]. In particular, for

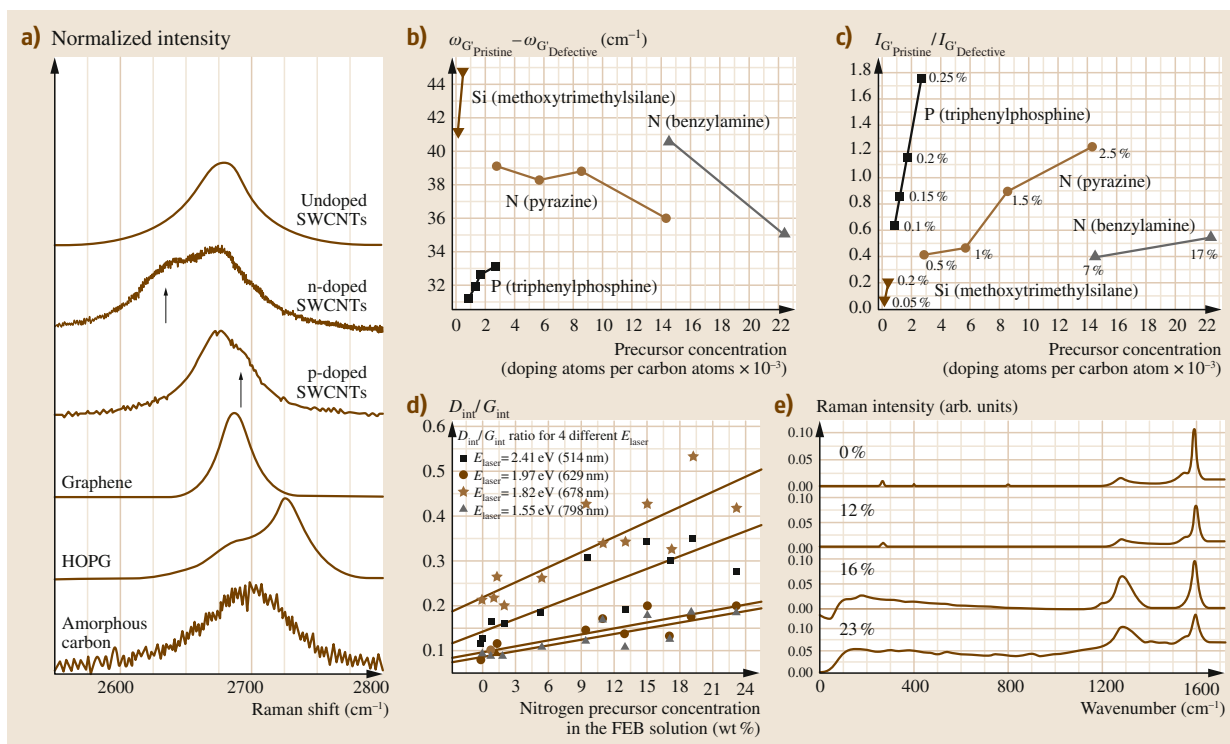

Fig. 6.19 (a) G' -band of different carbon nanostructures; here the doping of SWCNTs with boron and nitrogen: a new up-shift occurs for p-type doping (nitrogen atoms in SWCNTs), and a new downshift is observed for n-type doping (nitrogen atoms in SWCNTs; after [6.237]). Different precursors have been used to induce nitrogen, phosphorus, and silicon doping in SWCNTs, and the Raman spectra exhibit G-band shifts (b) as well as intensity variations (c), that are characteristic of each precursor used to prepare the SWCNT samples (after [6.239]). (d) Modifications of CNTs due to nitrogen doping (FEB – ferrocene/ethanol/benzylamine) (after [6.123]) and (e) dichlorocarbene functionalization of CNTs (after [6.242])

boron-doped CNTs the relative intensities D/D^* and G/D^* (where D^* is the second-order mode) increase with the density of defects [6.246].

The position of the modes has also been used to determine other types of modifications of CNTs; for example, when intercalating K and Li in SWCNTs, there is a downshift of the tangential phonon mode, and this shift appears to be reversible. This is due to electron-phonon coupling and/or local disorder in the dopant distribution [6.247]. Raman spectroscopy has also been used to monitor the oxidation process (e.g., carboxyl functionalization) by the observation of upshifts in the Raman modes [6.248].

6.5.6 Thermogravimetric Analysis

In thermogravimetric analysis (TGA), the weight loss is monitored as the sample is heated in a specific at-

mosphere. Generally, carbon nanotubes are subjected to thermal oxidation monitored by TGA in order to observe variations in their reactivity as a function of temperature. Nitrogen-doped SWCNTs have shown a lower thermal decomposition temperature compared with pristine SWCNTs [6.123]. It has also been observed that nitrogen- and boron-doped DWCNTs decompose at lower temperature compared with pure carbon DWCNTs (Fig. 6.20a) [6.249]. If carbon nanotubes are functionalized with polymers, TGA may provide evidence of different compounds burning at different temperatures, a fact that is consistent with the presence of polymers (Fig. 6.20b) [6.200]. The degree of functionalization has also been studied by TGA, where a greater amount of weight loss is usually attributed to side functional groups anchored on the surface of CNTs [6.223].

Different types of CNTs can result from different growth processes and conditions; the number of de-

Fig. 6.20a,b TGA plots of (a) pristine DWCNTs, and N- and B-doped DWCNTs in which the doped tubes exhibit a lower thermal decomposition temperature in air when compared with pure DWCNTs (after [6.249]). (b) MWCNTs functionalized with polystyrene (PS) showing greater weight loss (in nitrogen) caused by the presence of the polymer; (a) purified MWCNT, (b) MWCNT/PS, and (c) only polystyrene (after [6.200])

fects or side-groups may then vary. Therefore, TGA can be used to identify samples with a large number or defects or functional groups. In addition, high-temperature thermal annealing (e.g., 1500–2500 °C) of CNTs can be used to reduce the number of defects and increase the degree of crystallinity of the samples. This structural transition from defective

CNTs to highly crystalline CNTs has been studied by TGA. Here, the thermal decomposition temperature increases with higher thermal annealing temperatures. In addition, if there is a mixture of unannealed and annealed CNTs within the same sample, the resulting TGA plot is the sum of each separate TGA curve [6.250].

6.6 Applications of Modified Carbon Nanotubes

Modified CNTs can exhibit good electrical and chemical properties, and for this reason they have been used as electrodes for diverse applications such as in capacitors, fuel cells, solar cells, electron field-emission sensors, etc. In biology, modified CNTs are used as biomarkers, protein or microbial sensors, drug delivery agents for cancer treatments, etc. In this section, these applications are summarized.

In the case of electronic devices, N-doped CNTs can exhibit enhanced electron field emission, and this emission can be further improved if a high concentration of nitrogen atoms is located at the tip of the CNT, because these foreign atoms induce a well-known peak near the Fermi level [6.121, 122]. Experimentally, N-doped CNTs have exhibited relatively high emission currents

(10 mA/cm²) at fields of ca. 3 V/μm [6.251]. If a high degree of nitrogen defects are introduced into CNTs, the structure will exhibit lower potential barriers for electron field emission [6.252]. As previously discussed, this kind of doped CNTs also exhibits good catalytic activity for oxygen reduction in fuel cells, and has revealed good selectivity in the presence of methanol (Fig. 6.21a,b) [6.161, 222] and higher capacitance when compared with undoped CNTs (Fig. 6.21c) [6.124].

Modified CNTs have also been used to fabricate sensors. In a theoretical work, when a carbon nanotube exhibits –COOH groups, a hydrogen bond could appear with acetone, as observed by Robinson et al. [6.253]. This suggests that a functional oxygen group on a carbon nanotube may be useful to

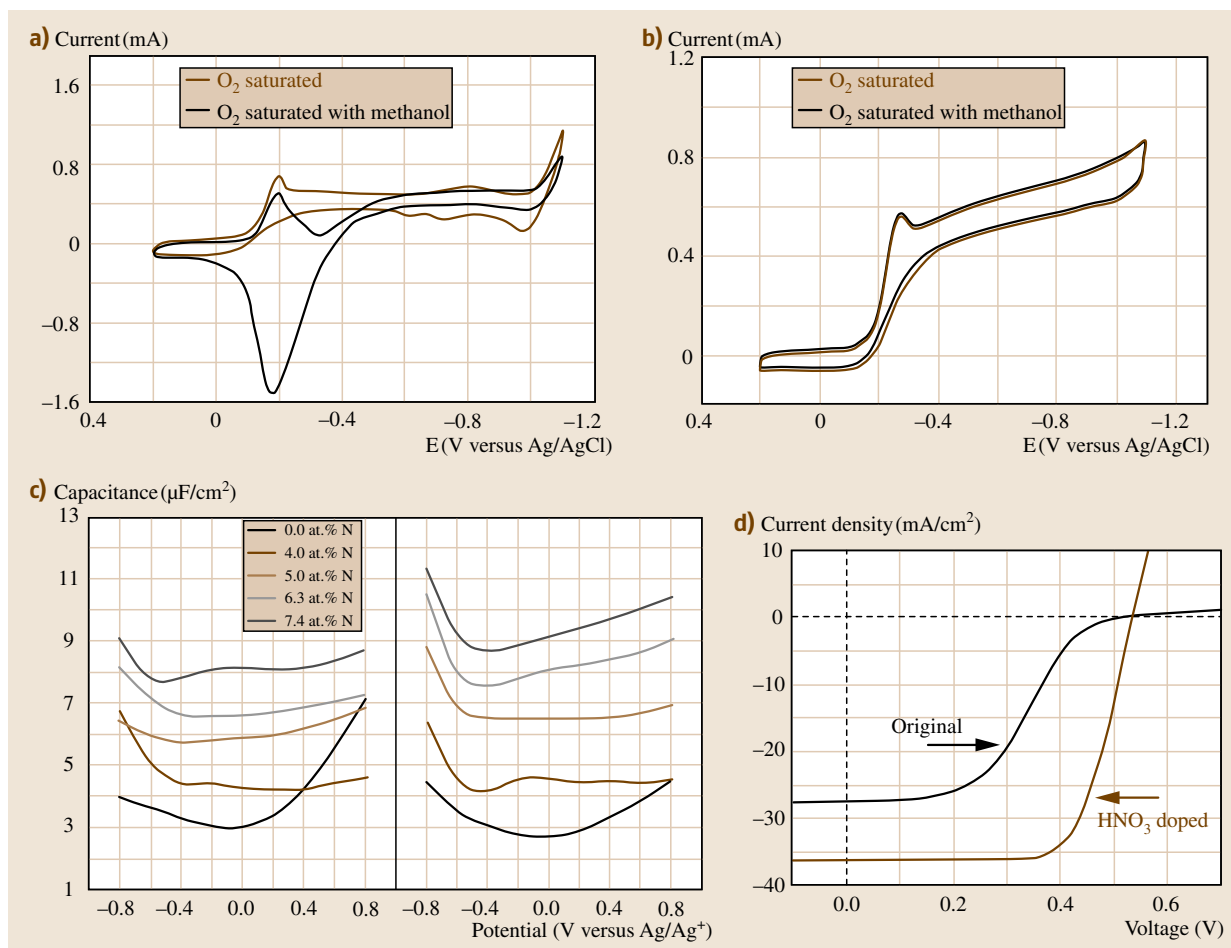

Fig. 6.21a–d Oxygen reduction observed by (a) Pt-C/glassy carbon, and (b) N-doped CNTs/glassy carbon electrodes. N-doped CNTs exhibit excellent selectivity in the presence of methanol (after [6.161]). (c) Enhanced capacitance by N-doped CNT mats that have been acid treated (left); untreated or pristine tubes are also shown for comparison (right; after [6.124]). (d) Improved short-circuit current density and filling factor obtained after treating CNTs with HNO_3 (after [6.258])

sense polar molecules. Regarding doping of carbon nanotubes with boron and nitrogen, it has been demonstrated that, when sensing CO and H_2O , boron-doped sites exhibit chemical adsorption whereas nitrogenated sites exhibit physical adsorption [6.254]. In another study, pyridine-like sites promoted chemisorption of molecules with OH groups [6.255]. When CNTs are doped with P there is a greater affinity towards acceptor molecules, and when CNTs are codoped with P and N atoms, the affinity towards donor molecules becomes strong, an effect caused by a partial positive charge located at the phosphorus atom [6.256].

Fig. 6.22 (a) Modified SWCNTs used as Raman tags in U87MG cancer cells (after [6.259]). Raman tags

U87MG

Cancer treatment

e) Cellular viability (%)

Experimentally, nitrogen-doped CNTs are capable of sensing acetone, ethanol, gasoline, chloroform, and ammonia. These devices show fast response on the order of tenths of a second [6.255]. In addition, sensors fabricated using SWCNTs covered with polyelectrolytes (nafion–ethanol or poly(sodium 4-styrene sulfonate)) and soaked on cotton fibers could efficiently detect albumin, a protein found in blood [6.257].

It has been observed that acid treatments shorten CNTs and functionalize their surface with carboxylic groups, thus allowing fabrication of homogeneous composites used in solar cells [6.262]. These kinds of CNTs have shown higher current densities than undoped CNTs [6.263]. In addition, fluorinated MWCNTs have been shown to improve the power conversion efficiency [6.262, 264]. Functionalization of CNTs is widely used to enhance the efficiency of solar cells, particularly of Si-based solar cells (Fig. 6.21d) [6.258]. CdSe nanoparticles have also been covalently anchored to carboxyl-functionalized SWCNTs and used for solar cell devices; the materials showed enhanced optical absorption [6.265].

In biological applications, it is important to modify CNTs in order for them to be dispersed in water suspension. Therefore, CNTs have been oxidized and wrapped with hydrophilic polymers [6.266–268], for example, with proteins, DNA, phospholipids, etc. [6.260, 269, 270]. Cycloadditions can also be carried out with azides [6.271, 272] or other dipolar compounds [6.273, 274]. These types of modified CNTs have been used as protein sensors [6.109, 275, 276] and as Raman tags able to detect low concentrations of analytes and biomarkers of human autoimmune diseases (Fig. 6.22a) [6.259].

6.7 Toxicity and Biocompatibility

The toxicity of CNTs has been studied for several years and is still not completely understood; this is because it depends on how the carbon nanotubes are modified either on their surface via functional groups (oxidation, doping, functionalization) or via external entities decorating them (phospholipids, nanoparticles).

Regarding the toxicity of CNTs in mice, there have been several studies showing that as-produced CNTs could be toxic when inhaled, affecting their lungs [6.286–289]. However, in vivo studies have shown that SWCNTs functionalized with polyethylene glycol intravenously injected into mice are excreted from the body, and no mortality was observed during the study [6.270]. In particular, hydroxylated SWCNTs

Phospholipid polyethylene glycol (PL-PEG)-modified SWCNTs have been used for near-infrared imaging in mice, in which the intrinsic near-infrared photoluminescence is detected at a low dose [6.277]. These conjugated systems can also be used as sensors in biological systems in which electron transfer between oxidative enzymes and the electrode surface takes place [6.140, 278, 279]. Finally, CNTs modified with chitosan have been used as microbial sensors, displaying higher sensitivity compared with a pure graphite electrode [6.280].

When functionalizing SWCNTs with specific proteins, they may be used to carry drugs to specific cells. It has been shown that SWCNTs modified with streptavidin are capable of penetrating human promyelocytic leukemia (HL60) cells and human T cells via endocytosis. However, streptavidin itself cannot enter the cells [6.281]. In another study, polyethylene glycol-modified SWCNTs loaded with doxorubicin (DOX) showed enhanced therapeutic efficacy and lower toxicity compared with DOX alone; when the DOX loaded on SWCNTs reaches the tumor cells, it is released due to the slightly acidic environment [6.282]. In addition, phospholipid polyethylene glycol moieties with folic acid terminal group have been attached to SWCNTs. These systems could then selectively enter cancer cells; once inside the cells, they can be irradiated with NIR lasers in order to heat the local environment, thus killing only cancer cells (Fig. 6.22b–d) [6.260]. It has also been found that P-glycoprotein-functionalized SWCNTs loaded with doxorubicin express 2.4-fold higher cytotoxicity with significant cell proliferation suppression towards K562R leukemia cells ($p < 0.05$) (Fig. 6.22e) [6.261].

Fig. 6.23 (a) B lymphocytes, (b) T lymphocytes, and (c) macrophages in presence of SWCNTs functionalized by 1,3-dipolar cycloaddition reaction (f-SWCNT); only the macrophages exhibit these f-SWCNT within the cytoplasm. (d) Cell viability of immune cells in presence of f-SWCNT without any effect (after [6.283]). (e) Nitrogen-doped and (f) undoped MWCNTs: cell viability of *Entamoeba histolytica*; here, the N-doped MWCNTs exhibited a higher degree of biocompatibility compared with undoped MWCNTs (after [6.284]). (g) Pristine SWCNTs biodegrade by oxidation with horseradish peroxidase with low concentrations of H_2O_2 ($\approx 40 \mu\text{M}$), after (h) 8 and (i) 12 weeks. tend to aggregate in the kidney, stomach, and bones of mice, being excreted via the renal route [6.290]. On the other hand, other studies have demonstrated that crystalline CNTs exhibit a lower degree of toxicity in mice compared with CNTs possessing structural defects (dangling bonds) and functionalities [6.291]. It is becoming more evident that the agglomeration and length of CNTs could affect their toxicity [6.286–289]. However, if CNTs are adequately modified, they may not be toxic [6.267, 281, 283, 292].

In vitro studies have also been carried out to understand how specific cell lines behave in the presence of modified CNTs. Human dermal fibroblasts have shown lower cytotoxicity with phenyl-SO₃H-functionalized SWCNTs. In addition, these modified SWCNTs did not exhibit any change in metabolic activity [6.293]. CNTs modified by the 1,3-dipolar cycloaddition reaction have been shown to be nontoxic to immunoregulatory cells, and PEG-functionalized CNTs obtained using an oxidation/amidation procedure cause secretion of proinflammatory cytokines by

macrophages (Fig. 6.23a–d) [6.283]. Regarding the toxicity of nitrogen-doped MWCNTs, they have been shown to be nontoxic for cultures of *Entamoeba histolytica*, however undoped MWCNTs exhibited the opposite effect (Fig. 6.23e,f) [6.284]. Furthermore, Ag nanoparticles have been anchored on hydroxyl-functionalized and N-doped MWCNTs and tested for biocompatibility. Although isolated Ag nanoparticles exhibit toxic activity, Ag nanoparticles anchored on N-doped and hydroxylated MWCNTs did not have significant effects on cellular functions [6.294]. A different study showed that metalloproteins could be more immobilized on acid-treated N-doped CNTs, possibly due to hydrogen bonds established between amino acid chains from the proteins and carboxyl functional groups of the carbon nanotubes [6.295]. For biomedical applications it is also important to know if CNTs are biodegradable. In this context, it has been observed that acid-treated SWCNTs could be degraded by enzymes with low concentration of H₂O₂; this biodegradation takes several weeks to accomplish (Fig. 6.23g–i) [6.285, 296].

6.8 Conclusions

Carbon nanotubes can be modified by doping with foreign atoms, incorporation of structural defects, and/or functionalization with different molecules. Doping can be endohedral (filling the tube core), exohedral (by intercalation of alkali metals among tubes), or in-plane (one or more heteroatoms being placed within the nanotube lattice). Structural defects include:

1. Introduction of pentagons, heptagons or octagons, changing the curvature of the structure
2. Bond rotations creating 5–7 pairs or Thrower–Stone–Wales (TSW) defects
3. Non-sp² defects such as adatoms, vacancies, edges, and interstitials, and
4. Curvature effects observed in narrow-diameter or collapsed nanotubes.

Functionalization of CNTs could be achieved via covalent modification, π – π interactions, or electrostatic interactions. Covalent modifications occur via oxidation, fluorination, aryl diazonium chemistry, azomethine ylides, reduction, carbenes, nitrenes, and radicals. π – π interactions are observed when non-polar molecules with aromatic rings or C=C bonds interact with the surface of carbon nanotubes. Finally,

electrostatic interactions can be enhanced by covalent functionalization in order to induce different charge on the tubes' surface.

Due to the local modification of the carbon nanotubes, they suffer significant changes in their electrical and chemical properties. The electrical properties can show an increase in electrical conductivity by electrons or holes. When CNTs are doped with conductive polymers or covalent bonding with redox mediators, they can exhibit faster response and higher electrochemical activity.

To improve understanding of how these modifications affect carbon nanotubes, several characterization techniques need to be used. The most common are high-resolution transmission electron microscopy (HRTEM) to view the atomic lattice, atomic force microscopy (AFM) to visualize the topography or phase differences, scanning transmission microscopy (STM) to improve understanding of how the electrons are distributed on the surface, electron energy loss spectroscopy (EELS) to study the charge distribution and the type of bonds involved in certain regions, x-ray photoelectron spectroscopy (XPS) to provide information related to the bonding environment within the surface, Raman spectroscopy to reveal the vibrational modes of carbon

nanotubes, and thermogravimetric analysis (TGA) to determine the thermal reaction weight loss under different atmospheres.

To decrease the toxicity of carbon nanotubes, they can be modified to improve their dispersibility

and prevent agglomeration; some CNTs with covalent functionalization, cycloaddition, and doping have also shown lower toxicity. Many studies show that, with appropriate modification, carbon nanotubes can be made more biocompatible.

6.9 Outlook and Perspectives

CNTs possess fascinating electrical and mechanical properties, and they are good candidates to be used in composites, and electronic and biomedical devices. Regarding electron field emission, N-doped CNTs are expected to exhibit good performance [6.251, 252]. Electronic sensors could also be fabricated, and these devices could efficiently sense various vapors or gases [6.253–257]. Similarly, modified CNTs could be used in biological sensors [6.259, 275, 276, 280] and solar cells with higher power conversion efficiency and better optical absorption [6.258, 262–265].

In biology and medicine, modified CNTs have been demonstrated to be useful in near-infrared imaging [6.277], investigation of the electron transfer properties of proteins, enzymes, and microbes [6.140, 278–280], drug delivery [6.281, 282], and even cancer treatments [6.270]. Regarding their toxicological aspects and biocompatibility, further investigations are needed, since their morphological, structural, and chem-

ical properties appear to determine how they interact with cells and tissues [6.261, 281, 282]. Several studies have demonstrated that modified CNTs are less toxic compared with undoped (pristine) CNTs [6.283, 292, 293, 295]. Furthermore, modified CNTs could be efficiently biodegraded by certain enzymes [6.285, 296]. This result ensures that CNTs will not have a long-term presence in biological systems.

Due to the increasing number of applications and commercial products based on CNTs, it is also important to improve their characterization techniques and identify more precisely their surface functionalities and precise reactivity. By increasing the spatial resolution of current instruments, one could detect and quantify (at atomic scale) the type of dopant (or functional groups) on the surface of CNTs. Based on these improved characterization techniques, one could then start setting up standards for carbon nanotubes. In this way, various applications could then be realized worldwide.

Carbon Nano

7. Carbon Nanofibers

Yoong A. Kim, Takuya Hayashi, Morinobu Endo, Mildred S. Dresselhaus

Carbon nanofibers are sp^2 -based linear, noncontinuous filaments that are different from carbon fibers, which are continuous with diameter of several micrometers. This chapter provides a review on the growth, structural properties, and practical applications of carbon nanofibers as compared with those of conventional carbon fibers. Carbon nanofibers can be produced via catalytic chemical vapor deposition (CVD) as well as the combination of electrospinning of organic polymer and thermal treatment. The amount of commercially available carbon nanofiber worldwide is ca. 500 t/year. Carbon nanofibers exhibit high specific area, flexibility, and superstrength due to their nano-sized diameter, which allows them to be used in electrode materials of energy storage devices, hybrid-type filler in carbon-fiber-reinforced plastics, and bone tissue scaffold. It is envisaged that carbon nanofibers will be key materials of green science and technology through a close combination with carbon fibers and carbon nanotubes.

Carbon nanofibers could be defined as sp^2 -based linear filaments with diameter of ca. 100 nm that are characterized by flexibility and their aspect ratio (above 100). Materials in fiber form are of great practical and scientific importance. The combination of high specific area, flexibility, and high mechanical strength allows nanofibers to be used in our daily life as well as in fabrication of tough composites for vehicle and aerospace applications. However, carbon nanofibers should be distinguished from conventional carbon fibers [7.1–3] and vapor-grown carbon fibers (VGCFs) [7.4–10] in their small diameter (Fig. 7.1).

Conventional carbon fibers and VGCFs have diameters of several micrometers (Fig. 7.1c,d). In addition, carbon nanofibers are different from well-known carbon nanotubes [7.5, 11–14]. Carbon nanofibers can be grown by passing carbon feedstock over nano-sized metal particles at high temperature [7.4–10], which is very similar to the growth conditions for carbon nanotubes. However, their geometry is different from concentric carbon nanotubes containing an entire hollow core, because they can be visualized as consisting of regularly stacked, truncated conical or planar layers along the filament length [7.15–18].

Fig. 7.1 Schematic comparison of the diameter dimensions on a log scale for various types of fibrous carbon materials

This unique structure endows them with semiconducting behavior [7.19] and chemically active end planes on both the inner and outer surfaces of the nanofibers, thereby making them useful as supporting materials for catalysts [7.20], reinforcing fillers in polymeric composites [7.21], hybrid-type fillers in

carbon-fiber-reinforced plastics [7.22–24], and photocurrent generators in photochemical cells [7.25, 26].

Alternatively, carbon nanofibers can be fabricated by the right combination of electrospinning of organic polymers and thermal treatment in an inert atmosphere. The electrospinning technique has been considered to be one of the advanced fiber formation techniques from polymer solution by using electrostatic forces [7.27–30]. Nanofibers produced by electrospinning exhibit noticeably different properties, such as nanosized diameter, high surface area, and thin web morphology, which make them applicable for fabrication of high-performance nanocomposites, tissue scaffolds, and energy storage devices [7.31–37].

Within this context, intensive studies on the synthesis, characterization, and possible applications of carbon nanofibers have been carried out during the last decade. In this chapter, we review their synthesis techniques and interesting textural properties, as well as promising applications of carbon nanofibers that have been developed over the past 10 years.

7.1 Similarity and Difference Between Carbon Fibers and Carbon Nanofibers

Since carbon nanofibers could be considered as a one-dimensional (1-D) form of carbon, their structure and properties are closely related to those of other forms of carbon, especially to crystalline three-dimensional graphite, turbostratic carbons, and to their constituent two-dimensional (2-D) layers. Therefore, several forms of conventional carbon materials should be mentioned in terms of their similarities and differences relative to carbon nanofibers. Especially, direct comparison should be made between fibrous carbon materials, because carbon fibers act as a bridge between carbon nanofibers and conventional bulk carbon materials. In this section, the structures of carbon fibers as well as VGCFs are described, with strong emphasis on the similarities and differences of these 1-D carbon materials.

7.1.1 Basic Concepts

Carbon fibers represent an important class of graphite-related materials that are closely related to carbon nanofibers with regard to structure and properties. Carbon fibers have been studied scientifically since the late 1950s, and fabricated industrially since 1963. They

are now becoming a technologically and commercially important material in aerospace, construction, sports, electronic device, and automobile industries. The global carbon fiber market has now grown to about 12 500 t/year of product, after 40 years of continuous research and development (R&D) work [7.1–3]. Carbon fibers are defined as a filamentary form of carbon with an aspect ratio (length/diameter) greater than 100. Probably, the earliest documented carbon fibers are the bamboo-char filaments made by Edison for use in the first incandescent light bulb in 1880. With time, carbon fibers were replaced by more robust tungsten filaments in light bulb applications, and consequently carbon fiber R&D vanished at that early time. However, in the late 1950s, carbon fibers once again became important because of the aggressive demand from the aerospace industry for lightweight, strong composite materials, in which carbon fibers are used as a reinforcement agent in conjunction with plastics, metals, ceramics, and bulk carbon materials. The specific strength (strength/weight) and specific modulus (stiffness/weight) of carbon-fiber-reinforced composites explain their importance as engineering materials,

due to the high performance of their carbon fiber constituents.

Since the temperature and pressure necessary to prepare a carbon fiber from the liquid phase is at the triple point ($T = 4100\text{ K}$, $p = 123\text{ kbar}$), it would be almost impossible to prepare carbon fibers from the melt under industrial processing conditions. Carbon fibers are therefore prepared from organic precursors. This preparation is generally done in three steps, including stabilization of a precursor fiber in air (at $\approx 300^\circ\text{C}$), carbonization at $\approx 1100^\circ\text{C}$, and subsequent graphitization (at $> 2500^\circ\text{C}$). Fibers undergoing only the first two steps are commonly called *carbon fibers*, while fibers undergoing all three steps are called *graphite fibers*. Carbon fibers are generally used for their high strength, while graphite fibers are used for their high modulus. Historically, Bacon's graphite whisker (Fig. 7.2) has demonstrated the highest mechanical properties of a carbon fiber (with regard to both strength and modulus), comparable to the ideal value for a graphite network [7.38]. Graphitic whiskers were grown under conditions near the triple point of graphite. Then, a structural model was proposed in which layers consisting of graphene sheets are wound around the axis as if rolling up a carpet. These whiskers were used as the performance target in the early stages of carbon-fiber technology, even though they have never been produced on a large scale.

Fig. 7.2 Model for graphite whiskers grown by direct-current (DC) arc discharge of graphite electrodes. Whiskers were reported to have a carpet-rolling structure of graphite sheets with high mechanical strength and modulus along the fiber axis, similar to the ideal values of a graphene sheet

7.1.2 Synthesis and Properties of Carbon Fibers

Scanning electron microscopy (SEM) images together with schematic structural models are shown in Fig. 7.3 for typical carbon fibers: a high-strength polyacrylonitrile (PAN)-based fiber (Fig. 7.3a), a high-modulus PAN-based fiber (Fig. 7.3b), and a mesophase pitch-based carbon fiber (MPCF) (Fig. 7.3c) [7.38, 39]. The PAN-based fibers consist of small sp^2 -carbon structural units preferentially aligned with the carbon hexagonal segments parallel to the fiber axis. This orientation is responsible for the high tensile strength of PAN-based carbon fibers [7.40]. By varying the processing conditions (e.g., oxidation conditions, choice of precursor material, and especially by increasing the heat treatment temperature) of PAN fibers, better alignment of the graphene layers can be achieved (structural model of Fig. 7.3b), thus leading to stiffer, higher-modulus PAN fibers, but with lower strength [7.39]. PAN-based fibers are one of the typical hard carbons. MPCFs consist of well-aligned graphitic layers arranged nearly parallel to the fiber axis, and this high degree of preferred orientation is responsible for their high modulus or stiffness as well as their relatively high graphitizability. The structures described above give rise to different physical properties, although each type of fiber features hexagonal carbon networks, possessing the strongest covalent bonds in nature (C–C bonds). These strong interatomic bonds lie in sheets essentially parallel to the fiber axis and are responsible for the high mechanical performance of these carbon fibers.

Referring to Fig. 7.4a, we see that PAN-based fibers have high strength and MPCFs have high modulus, while VGCFs provide mainly ultrahigh-modulus materials [7.4, 41]. In this figure we also observe isotropic pitch-based (general grade) fibers, exhibiting much lower modulus and strength, but widely used in composites with cement matrix for construction due to their low cost and high chemical stability. Figure 7.4b demonstrates a direct indication of the differences in the mechanical properties of various carbon fibers, from low-modulus high-strength to high-modulus low-strength fibers, from the lower left to the upper right in the photograph, where a yarn containing 500 fibers was initially placed in a horizontal position. These fibers are combined with other materials in order to design suitable mechanical properties, and the fibers are used as a filler for various advanced composite materials. To obtain high performance in carbon and graphite fibers, it is very important to control the

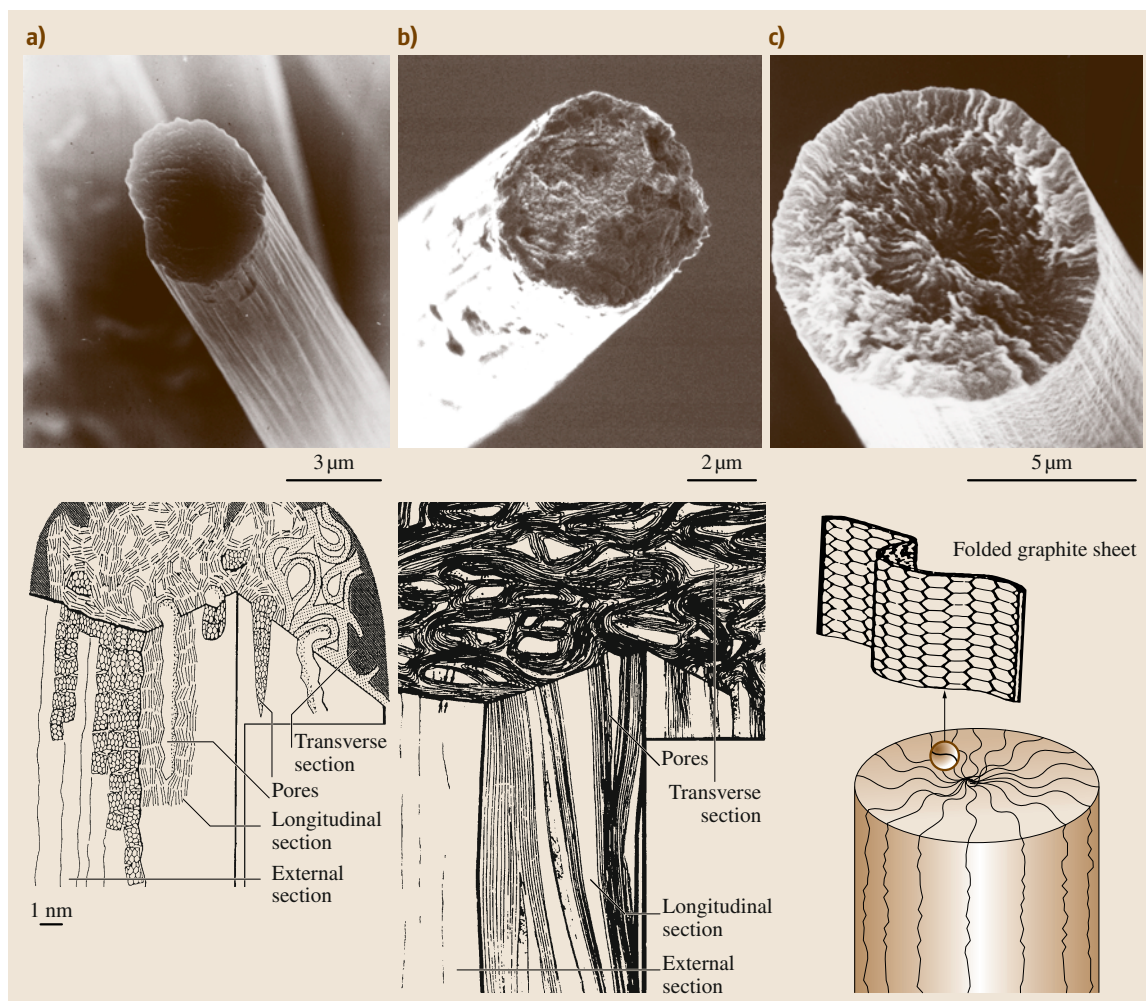

Fig. 7.3a–c SEM micrographs of three types of carbon fibers and corresponding structural models: (a) high-strength PAN-based fiber, (b) high-modulus PAN-based fiber, and (c) a mesophase pitch-based fiber. In the *second row*, for each fiber type, a schematic diagram of the fiber structure is shown

microstructure and nanostructure by selecting the appropriate organic precursor as well as the processing conditions.

7.1.3 Vapor-Grown Carbon Fibers

VGCFs have a very special structure like annular rings on a tree (Fig. 7.5a) and are synthesized by a somewhat different formation process than that used to produce PAN-based and MPCFs. In particular, VGCFs are not prepared from a fibrous precursor, but rather from hydrocarbon gas, using a catalytic growth process outlined in Fig. 7.5b [7.5–10]. Ultrafine transition-metal par-

ticles, such as iron particles with diameter less than 10 nm, are dispersed on a ceramic substrate, and a hydrocarbon, such as benzene diluted with hydrogen gas, is introduced at temperatures of about 1100 °C. Hydrocarbon decomposition takes place on the catalytic particle, leading to continuous carbon uptake by the catalytic particle and continuous output by the particle of well-organized tubular filaments of hexagonal sp^2 carbon. The rapid growth rate of several tens of $\mu\text{m}/\text{min}$, which is 106 times faster than that observed for the growth of common metal whiskers [7.37], enables production of commercially viable quantities of VGCFs. Evidence in support of this growth model is provided

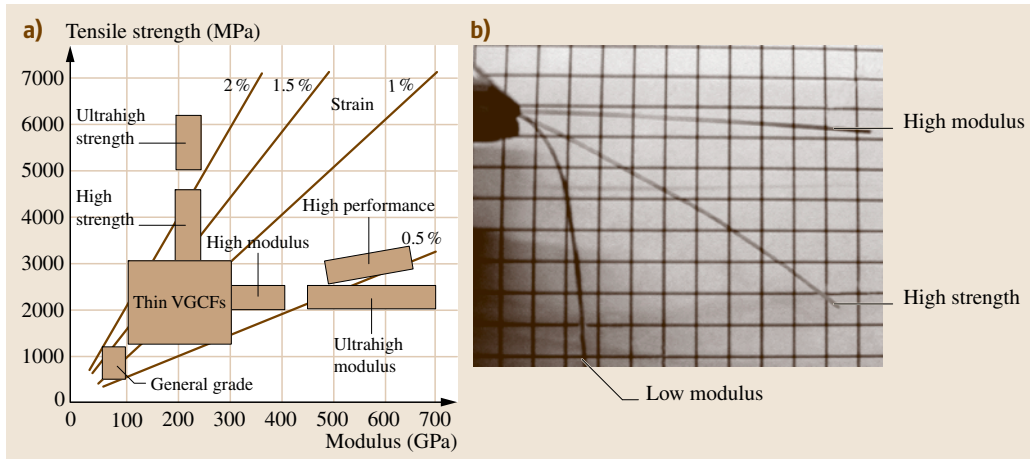

Fig. 7.4 (a) Mechanical properties of various kinds of carbon and graphite fibers, and (b) direct comparison of the mechanical properties for high-strength and high-modulus fibers. A low-modulus fiber droops under its own weight, whereas high-modulus fibers do not

Fig. 7.5 (a) SEM image of vapor-grown carbon fibers, (b) suggested growth mechanism of VGCFs using ultrafine catalytic metal particles, (c) very early stage of tubule growth in which the catalytic particle is still active, promoting elongation. The primary tubule thus formed acts as a core for vapor-grown fibers. (d) The fiber is obtained through a thickening process, such as pyrolytic deposition of carbon layers on the primary tubule. The encapsulated catalytic particle can be seen at the tip of the hollow core

Fig. 7.6 (a) Carbon nanotube exposed at the broken end of a vapor-grown carbon fiber: (a) as grown, and (b) heat-treated at 3000 °C. The sample is fractured by pulverization, and the core diameter is ≈ 5 nm. These images suggest a structural discontinuity between the nanotube core of the fiber and the CVD-deposited carbon layers, and also show the strong mechanical properties of the nanotube core, which maintains its form after breakage

by the presence of catalytic particles at the tips of the resulting VGCFs (Fig. 7.5c) [7.38]. The primary hollow tubule is first formed by the catalytic process (with a diameter of less than several nanometers), and the tubule is then thickened by a successive chemical vapor deposition (CVD) process, corresponding to deposition of pyrolytic carbon layers on the primary tubular core (Fig. 7.5d).

Interestingly, at the center of the annular ring structure, we can clearly observe an extruded carbon

nanotube (with diameter ≈ 5 nm) (Fig. 7.6a), which serves as a template for growing the thicker carbon fiber [7.42]. This tubular core implies a discontinuity in the structure between the core and the thickened periphery of the carbon fiber. Such a discontinuity in the structure is retained even after heat treatment at temperatures as high as 3000 °C. This graphitization process introduces a fully developed graphite structure in the peripheral region of a VGCF, exhibiting a polygonal shape (Fig. 7.6b).

7.2 Growth and Structural Modifications of Carbon Nanofibers

This section presents how carbon nanofibers are fabricated, and their morphological and physicochemical modifications by post treatments are presented in relation to their microstructure. We give an overview of two different synthetic methods: the catalytic chemical vapor deposition method, and the combination of electrospinning with subsequent thermal treatment.

7.2.1 Catalytically Grown Cup-Stacked Type

A catalytic thermal chemical vapor deposition synthesis method has been extensively investigated as a promising method for large-scale production of carbon nanotubes and carbon nanofibers [7.43–45]. Through precise control of the synthesis conditions, it is possible to tailor the diameter, crystallinity, and also orientation of the cone angle with respect to the fiber axis [7.46–48]. Carbon nanofibers with a large hollow core and a large portion of open edges at the outer surface and also in the inner channels, due to the truncated graphene cone morphol-

ogy (cup-stacked), are characterized in terms of their microstructure, oxidation behavior, and also graphitizability, and are compared with those of conventional tubular types of carbon nanofibers. These structural characteristics as well as their potential low production cost using a floating reactant production system may make it possible to use such carbon nanofibers in the fabrication of absorbent materials, catalyst supports, field emitters, gas storage components, and composite materials.

Field-emission scanning electron microscopy (FE-SEM) and transmission electron microscopy (TEM) images at low magnification (Fig. 7.7a,b) reveal relatively long and straight carbon nanofibers with a hollow core along the fiber length (Fig. 7.7c), which exhibit diameters ranging from 50 to 150 nm and lengths up to 200 μm . One of the main characteristics of these fibers is a large hollow core, as compared with conventional tubular-type nanofibers. In addition, we can find some differences in the ratio of the outer

Fig. 7.7 (a) FE-SEM image of nanofibers showing a long and straight morphology; (b) TEM image of nanofibers with a hollow core at low resolution; (c) TEM image of uncoated nanofibers with a large hollow core; (d) TEM image of coated nanofibers with a large hollow core; (e) HRTEM image of an uncoated nanofiber (*inset* shows a schematic model of a carbon nanofiber); (f) HRTEM image of a coated nanofiber

diameter to the inner diameter, i.e., the wall thickness of the carbon nanofibers, as shown in the TEM images of Fig. 7.7c,d. To study these differences in detail, high-resolution TEM (HRTEM) studies have been carried out for these two types of samples. One type of nanofiber shows a truncated cone microstructure (Fig. 7.7e), whereas the other type of nanofiber contains a certain portion of amorphous carbon (coated structure) (Fig. 7.7f). The truncated cone angle (cup) with regard to the fiber axis, measured by electron diffraction (ED), taking the fast Fourier transform (FFT) of several TEM images, lies mainly between 45° and 80° . The observation of (110) planes of graphite might be due to a superposition of conical graphene sheets with ABAB stacking. In terms of the growth mechanism, uncoated nanofibers (Fig. 7.7e), consisting of stacked conical

graphene sheets, are primarily formed by catalytic effects, while the outer part of the coated nanofiber (Fig. 7.7f) corresponds to amorphous carbon deposited during the secondary thickening growth process.

To understand the unique properties of these novel nanofibers, such as a large hollow core and a conical morphology, it is indispensable to mention the morphology of the catalytic metal particles used in the growth process. It has been clearly shown that the microstructure of the nanofibers is determined by the shape of the metal particle at the tip of the fiber (Fig. 7.8a,b). Carbon derived from the decomposition of hydrocarbons dissolved in the metal particle might precipitate as graphitic carbon. This carbon replication from metal particles results in the formation of stacked truncated cones, which grow graphitic nanofibers [7.48]. Along

Fig. 7.8 (a) HRTEM image of a typical metal particle at the tip of the nanofibers; (b) and (c) enlarged HRTEM images. (Note that the truncated conical graphene sheets replicate the shape of the rear part of the metal particle)

the fiber axis (Fig. 7.8c), there are some disordered and wavy regions, which might be due to the relaxation of carbon layers as a result of cooling [7.49]. Based on this study, it is possible to say that the size of the metal particle in the growth direction of the fiber is directly related to the size of the hollow core, which is also determined by the composition of the catalytic particle, the type of carbon feedstock, and the reaction temperature.

The outer and also inner surfaces of the nanofiber have to be covered entirely by open edges, i.e., the end face of the graphitic conical sheets from the point of view of the growth mechanism. Practically, the deposi-

tion of amorphous carbon on the catalytically induced graphitic carbon phase, which is unavoidable in the synthetic process of nanofibers, and also the possible formation of loops between adjacent conical graphene sheets might deteriorate the total chemical and physical reactivity of the nanofibers. To solve this problem, an air oxidation process is applied to prepare nanofibers with an increased fraction of open edge sites. Figure 7.9a shows Raman spectra for oxidized uncoated nanofibers (Fig. 7.7c,e) at different temperatures. Modification of the surface of the nanofiber starts at 520 °C, and then the optimal oxidation temperature is found to be at 530 °C for our experimental conditions, based on a decreased half-width at half-maximum (HWHM) and intensity of the D peak at 1355 cm⁻¹ (the defect mode), the appearance of a shoulder peak at 1620 cm⁻¹, and also a decreased relative intensity (I_D/I_G). When oxidized at 540 °C, structural disruption might occur, due to severe oxidation, based on an increased intensity of the D peak and also a large value of the relative intensity ($I_D/I_G = 0.9674$). For the case of an optimally modified sample (530 °C), consistent fiber morphology (Fig. 7.9b) and a somewhat decreased wall thickness (Fig. 7.9c) are observed, accompanying an increase in the specific surface area from 49.67 to 146.47 m²/g.

The graphitization process is known as one of the most efficient ways to modify the microstructure of carbons [7.50, 51]. TEM images of graphitized nanofibers are shown in Fig. 7.10. The most interesting change caused by the graphitization process is a morphological transformation from a smooth-walled tubule type to a reversing sawtooth type with regular pitch (Fig. 7.10a,b,d). The other features of the graphitized nanofibers are the formation of long links along the outer and inner sides of the fibers at regular pitch intervals (closure of open cups on both sides) and loop formation between neighboring conical sheets (Fig. 7.10c,e), resulting in the formation of triangle-type nanomaterials (Fig. 7.10f). Also, the morphologies of the graphitized samples are strongly affected by the microstructure of the starting materials (Fig. 7.10b from an uncoated nanofiber and Fig. 7.10d from a coated nanofiber). For the graphitization mechanism, the decrease in interlayer spacing [from 3.45 to 3.395 Å, based on x-ray diffraction (XRD) analysis] is smaller than that of CVD-based carbon materials. In fact, the number of loops increases with increasing heat treatment temperature. Therefore, the formation of loops in both the inner and outer surfaces of the nanofiber might retard the three-dimensional stacking ordering caused by mass transformation, and also give indirect evidence

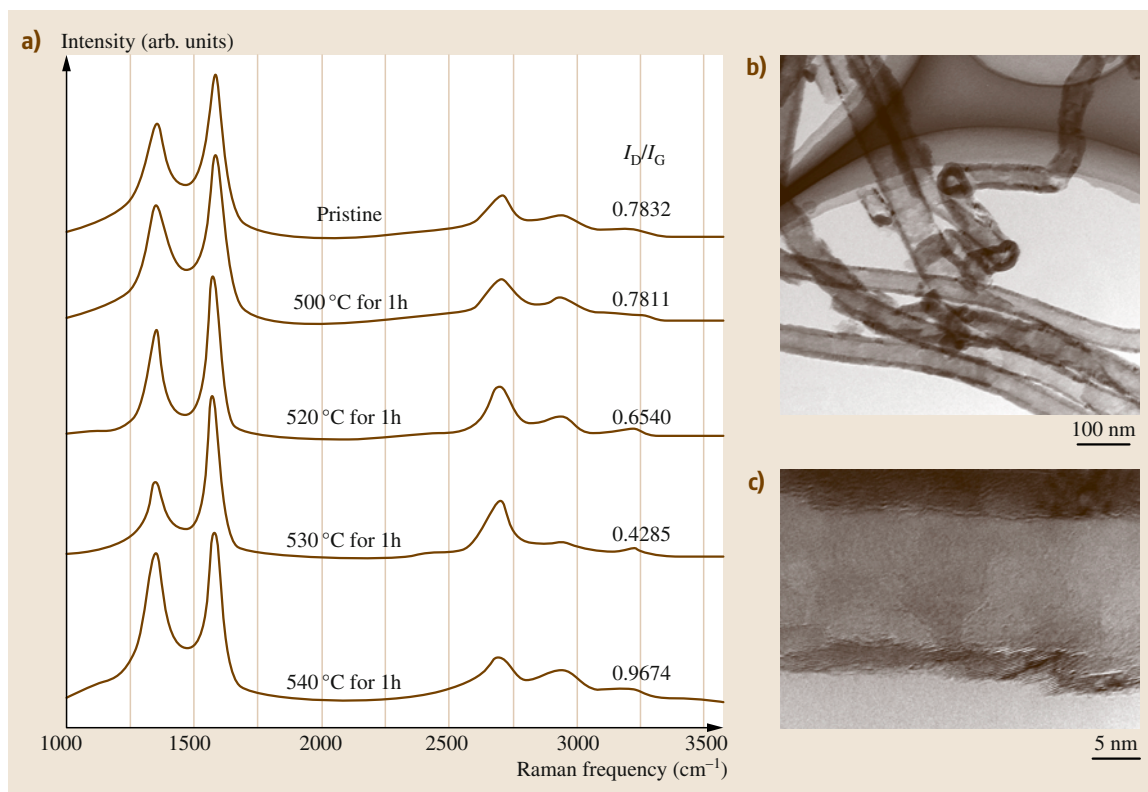

Fig. 7.9 (a) Raman spectra of nanofibers oxidized at different temperatures in air atmosphere for 1 h (I_D/I_G is the relative intensity ratio of the G peak over the D peak). (b) TEM image of nanofiber morphology for experimental condition at 530 °C, (c) high resolution TEM image of nanofiber showing decrease in wall thickness, and an increase in specific surface area

for the carbonization and graphitization mechanism of hard carbon materials.

7.2.2 Catalytically Grown Platelet Type

SEM and TEM studies reveal that carbon nanofibers have the form of short rods (Fig. 7.11a) with semirectangular cross-sectional morphology (inset to Fig. 7.11a). Moreover, crystalline graphene layers are stacked regularly along the length direction of the carbon nanofiber (Fig. 7.11b), the accessible surface area of which is fully covered with chemically active end planes. When an undoped sample was thermally treated in argon at 2200 °C and 2500 °C, the active edges were structurally converted to energetically stable multiloops (Fig. 7.11c). For the undoped sample, multiloop formation was not clearly observed at 1900 °C. In contrast, we clearly observed formation of multiloops in a boron-doped sample treated at 1900 °C. In addition, the B-doped sample

treated at 2500 °C (Fig. 7.11f) had a higher number of multiloops than did the corresponding undoped sample (Fig. 7.11d). Therefore, we assume that B atoms play an important role in loop formation, leading to changes in the surface morphology of carbon nanofibers during high-temperature thermal treatment.

We carried out x-ray diffraction (Fig. 7.12a,b) and Raman spectroscopy (Fig. 7.12c,d) studies to investigate the changes in the structure of carbon nanofibers that result from high-temperature thermal treatment in the presence of B atoms. The sharp (002) line for the as-grown sample indicates the relatively high crystallinity of the catalytically grown carbon nanofibers (Fig. 7.12a). As the heat treatment temperature is increased for the undoped sample, the (002) line shifts to higher angles. The decreased HWHM of the D band (defect-induced mode) at 1350 cm^{-1} and the G band (E_{2g2} graphitic mode) at 1580 cm^{-1} , as well as decreased R value (intensity of the D band/intensity of

Fig. 7.10 (a), (b), (c) HRTEM images of a graphitized uncoated nanofiber [starting material is uncoated nanofiber (Fig. 7.1c,e)]; (d), (e), (f) HRTEM images of a graphitized coated nanofiber

the G band) in the Raman spectra (Fig. 7.12c and Table 7.1) indicate that the structure of the undoped carbon nanofibers was improved by the high-temperature thermal treatment. Even though the undoped nanofibers were thermally treated at 2500 °C in argon, there was no splitting of the (101) and (100) lines in the x-ray diffraction patterns; furthermore, no distinctive reduction in the intensity of the D band was observed in the Raman spectrum for the undoped sample. This result

can be explained by the formation of stable multiloops on the outer surface of the carbon nanofibers (TEM images in Fig. 7.11), which effectively inhibited three-dimensional stacking [7.52]. In the case of B-doped carbon nanofibers, we observed highly improved structures upon thermal treatment at high temperatures (Fig. 7.12b, and lower value of interlayer spacing in Table 7.1), reflecting the fact that B atoms are graphitization accelerators in carbon materials. Recently, it was reported that resonance Raman spectroscopy is extremely sensitive to the end planes in graphitic nanoribbons [7.53]. It is well known that the Raman line at 1620 cm^{-1} in the as-grown sample originates from the end planes in carbon materials [7.54]. With increasing thermal treatment temperature, the Raman line at 1620 cm^{-1} disappears, which is consistent with the formation of energetically stable multiloops at the end planes. However, the high intensity of the D and D' bands as well as the high R values observed for B-doped samples (Fig. 7.12d) strongly indicate that the B atoms were incorporated into the sp^2 carbon network via substitution for carbon, because the B–C distance is slightly larger than the C–C distance [7.55]. Notably, the higher value of the HWHM of the G band (Table 7.1) (which is intrinsically related to phonon lifetime) indicates that the B atoms incorporated into the carbon network create optical defects. In addition, we have confirmed the presence of substitutional incorporation of B into carbon fibers by using x-ray photoelectron spectroscopy.

To evaluate the physical changes in the B-doped carbon nanofibers, we measured their electrical resistivity in the bulk state using a four-point probe method (Fig. 7.13a). After pouring a specific amount of the carbon nanofibers into the sample holder, we measured the volumetric resistivity at a nanotube mass density of 1.23 g/cm^3 . Generally, B-doped samples exhibited improved electrical conductivity compared with undoped samples. It is noteworthy that the electrical resistivity in the bulk state is determined by both the contact resistivity between fibers and the intrinsic resistivity of individual fibers. Therefore, we measured the electrical resistivity of a freestanding individual nanofiber using methods described in the relevant literature [7.56, 57]. After spin-coating a nanofiber suspension onto Au/Ti electrodes, we confirmed using FE-SEM that an individual fiber had bridged the electrode gap (500 nm). We then obtained the intrinsic resistivity of an individual nanofiber from a linear current–voltage relation up to 1 V. As shown in Fig. 7.13b, the electrical resistivity at room temperature of the individual as-grown

Fig. 7.11 (a) SEM and (b) TEM images of as-grown platelet-type carbon nanofibers. Inset shows the semirectangular cross-sectional morphology of the carbon nanofibers. Note that the crystalline graphene layers are stacked regularly along the length of the carbon nanofiber, the accessible surface area of which is covered with active edges. TEM images of samples thermally treated at (c) 2200 °C and (d) 2500 °C without B, and at (e) 1900 °C and (f) 2500 °C in the presence of B

carbon nanofiber was extremely high ($\approx 280 \text{ k}\Omega$) compared with an arc-based multi-walled carbon nanotube ($\approx 2.4 \text{ k}\Omega$) [7.58]. This result can be explained by the peculiar platelet-like morphology of the nanofibers investigated in the present study: the current flow between graphene layers in graphite (along the fiber length direction) is six times lower than that in the graphene plane (a -axis) [7.59]. Although no general relationship between thermal treatment temperature and the electrical resistivity of an individual fiber was observed (possibly due to the inhomogeneous diameter distribution), we confirmed that the substituted B atoms in the carbon nanofibers lowered the Fermi level, thus increasing the electrical conductivity of the carbon nanofibers.

In addition, we evaluated the effectiveness of the B-doped carbon nanofibers as an anode material for high-rate lithium-ion batteries (LIBs). We demonstrated that the substituted B atoms improve the electrical conductivity as well as give rise to multiloop formation, producing an outer surface that is stable against (or inert to) electrolytes. Figure 7.14a,b shows the voltage profiles of the second discharging/charging cycle for carbon nanofibers prepared under different conditions. The increased proportion of the lithium discharge/charge plateau below 0.2 V with increasing thermal treatment temperature (Fig. 7.14a) and B doping (Fig. 7.14b) indicates that Li insertion/desertion was the main mechanism and that the structural

integrity was improved. The large amount of Li adsorption onto B-substituted planar carbon materials has been theoretically confirmed by molecular-orbital calculations [7.60]; this improved Li adsorption is one reason for the improved discharge capacity of the B-doped carbon nanofibers, since B atoms act as an electron acceptor and induce redistribution of the π -electrons within loops. In addition, we found that the capacity of the B-doped carbon nanofibers degraded to a lesser extent at high discharge current density (Fig. 7.14c,d) compared with undoped samples. In other words, substituted B atoms within car-

bon nanofibers enhanced the electrical conductivity of individual carbon nanofibers as well as forming loop-ended surfaces that were stable against (or inert to) electrolytes.

7.2.3 Electrospun Carbon Nanofibers

Polyacrylonitrile (PAN) polymer in dimethylformamide (DMF) can be easily transformed into white-colored nanofiber web using our electrospinning conditions (Fig. 7.15a), because PAN has been widely used as a precursor for conventional carbon fibers. The con-

version of a PAN nanofiber to a carbon nanofiber involves stabilization and carbonization. Air stabilization of electrospun nanofiber ($\approx 280^{\circ}\text{C}$ for 1 h under controlled air circulation) is accompanied by a change in color from white to reddish brown (Fig. 7.15b). Finally, when an air-stabilized nanofiber web was thermally treated at 1000°C in an inert atmosphere (e.g., argon or nitrogen gas), the obtained black-colored car-

bon nanofiber web (Fig. 7.15c) exhibited a relatively high carbon yield (up to 40–50%). This oxidative stabilization is considered to be due to the introduction of thermosetting properties to the spun organic fibers, and involves oxygen uptake and subsequent complex chemical and physical reactions occurring on multiple time and temperature scales [7.61, 62]. Thus, the accessible surface area of a precursor will be the determining

Fig. 7.15a–c Photographs of PAN-derived (a) electrospun nanofiber web (light-gray color), (b) air-stabilized web (dark-brown color), and web thermally treated at 700 °C (black color). It is noteworthy that air stabilization is a critical step for obtaining dimensional stability of nanofibers

factor in terms of the chemical kinetics. To understand the oxidation behaviors in detail, differential thermal analysis was carried out for both micro-sized and nano-sized fibers in air atmosphere (Fig. 7.16). Both samples exhibited single exothermic peaks at around 320 °C, corresponding to oxygen uptake and the subsequent complex chemical reactions [7.61, 62]. The relatively sharp peak for the electrospun sample indicates that the oxygen-induced chemical reactions in nanosized fibers occur quickly at a specific temperature, as expected. Therefore, the theoretically twofold higher accessible surface area (as derived from the nanosized diameters) as compared with the micro-sized fibers ($\approx 10\ \mu\text{m}$) is quite favorable in decreasing the air stabilization time by a factor of two, because oxygen is believed to dif-

Fig. 7.16 Differential thermal analysis graphs of micro-sized and nanosized fibers in air atmosphere, respectively (heating rate 10 °C/min)

fuse from the outer surface of fibers kinetically. For our experimental conditions, optimally air-stabilized nanofiber was *flameproof* when the oxygen content was 8–10%.

FE-SEM images of electrospun PAN nanofibers (Fig. 7.17a,b) exhibit a very long and straight fibrous morphology with uniform diameters ranging from 200 to 300 nm (average 250 nm). In addition, nanofibers are partially aligned along the winding direction. When thermally treated at 700 °C, morphological changes from straight to undulated fibers (Fig. 7.17c,d) are caused by large weight loss (up to 30–40%) accompanied by gas evolution (e.g., CO, CO₂, H₂O etc.). For thermally treated nanofiber webs at 1000 °C (Fig. 7.17e,f), 1500 °C, 2000 °C, and 2500 °C, there were no large changes in macromorphology, as in typical nongraphitizable carbon materials. When thermally treated up to 2800 °C (Fig. 7.17g,h), the main changes are a morphological transformation from a round to faceted cross-sectional morphology and from a smooth to wrinkled surface, mainly due to large density changes resulting from the liberation of heteroatoms and densification of carbon atoms (see the specific gravity change from 0.690 to 1.999 in Table 7.2). It is well known that the structural development of conventional carbon materials during thermal treatment is a thermally activated kinetic process [7.63]. When considering the morphological changes of our nanosized fibers kinetically, compared with micro-sized ones, no large structural changes on isothermal treatment at 2500 °C and 2800 °C for various holding times ranging from 10 to 10–60 min are observed for our

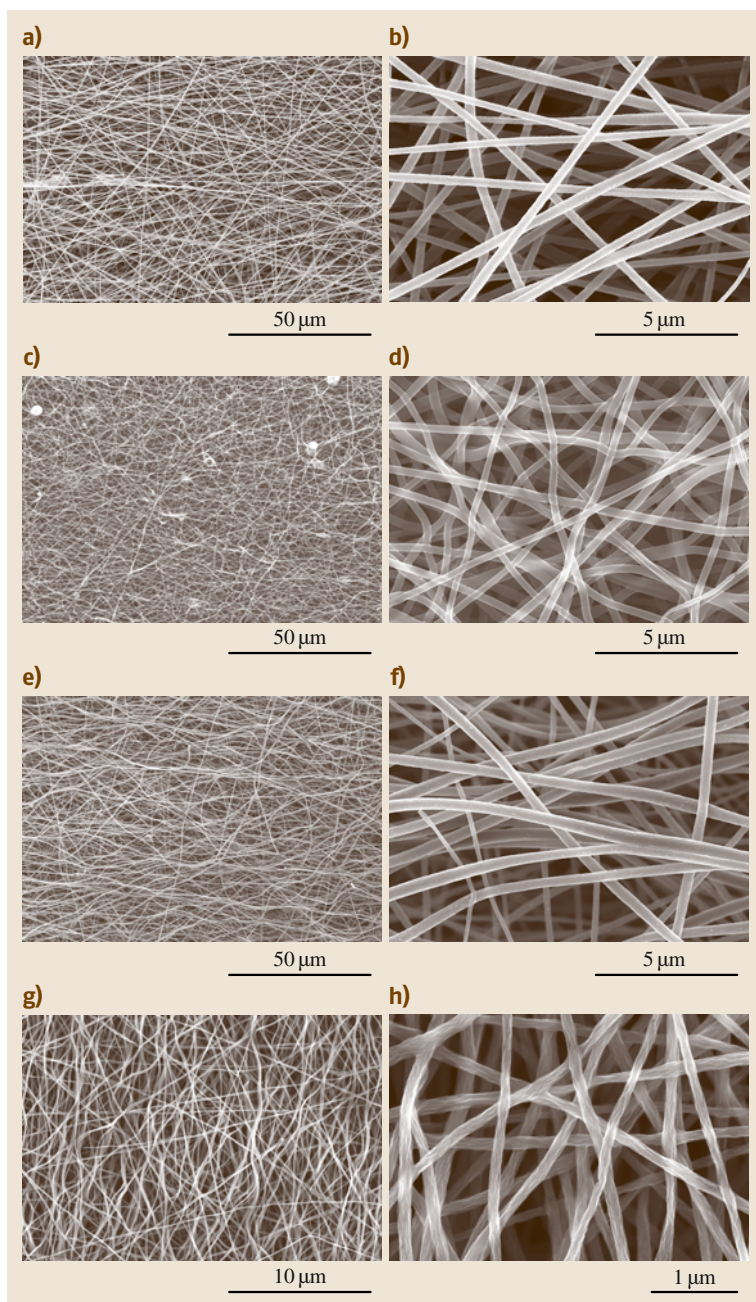

Fig. 7.17a–h FE-SEM images of (a,b) electrospun nanofibers thermally treated at (c,d) 700 °C, (e,f) 1000 °C, and (g,h) 2800 °C at different resolutions

electrospun nanofibers, because thermal energy is fully transferred to the inner part of the nanosized fibers within a short time. As a result, high-purity carbon nanofibers can be fabricated without disrupting the fiber morphology through the controlled combination

of electrospinning and thermal treatment, even when the electrospun nanofiber web is thermally treated up to 2800 °C.

The variations of structural changes on thermal treatment of electrospun nanofibers as a function

of heat treatment temperature have been studied by x-ray diffraction and microprobe Raman spectroscopy (Fig. 7.18a,b). The x-ray patterns near $2\theta = 25^\circ$ corresponding to the (002) layers of the graphite sharpen, and move to slightly higher angles for the sample at 2500 °C. In the Raman spectra (Fig. 7.18a), the increased intensity and decreased HWHM of the G band (E_{2g2} graphitic mode) at 1580 cm^{-1} , and also the decreased intensity and HWHM of the D band at 1355 cm^{-1} (defect-induced mode), with increasing thermal treatment temperature indicate the sequential structural development [7.64]. Even when thermally treated at 2800 °C, the absence of (100) and (004) lines (Fig. 7.18b) and the presence of D band and the appearance of D' band (1620 cm^{-1}) (Fig. 7.18a) indicate that PAN-derived nanofibers are typically nongraphiti-

zable carbon. Structural parameters including electrical conductivity and specific gravity are summarized in Table 7.2. Even though no large changes are observed in the structural parameters (interlayer spacing and crystallite size) by x-ray diffraction for samples heat treated between 1000 °C and 1500 °C, it is noteworthy that large changes in the *R* value (from Raman spectra) occurred for the same samples. In addition, an abrupt increase in electrical conductivity, by more than one order of magnitude, occurs in this region. This inconsistency results from the different analytical techniques used, because XRD provides average bulk structural information whereas Raman studies provide structural information within the optical skin depth ($\approx 10\text{ nm}$). Thus, it is possible to say that carbonization occurs from the outer surface to the inner part kinet-

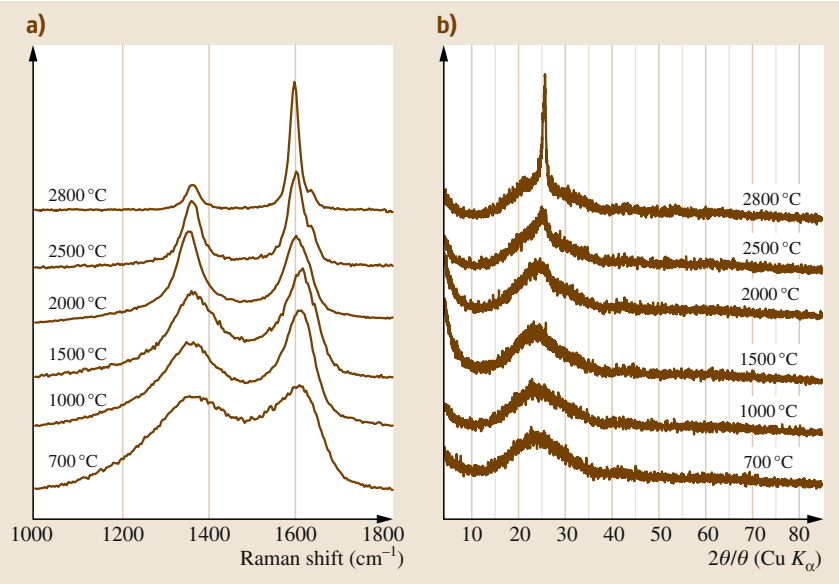

Fig. 7.18 (a) Raman spectra and (b) x-ray diffraction characterization of thermally treated nanofibers at various temperatures in the range 700–2800 °C

ically. Even though nanofiber web thermally treated at 2800 °C exhibits a relatively well-developed texture, the greatly decreased electrical conductivity (from 55.41 to 20.15 S/cm) is thought to be due to contact points between nanofibers due to abrupt volume changes. These structural parameters are not independent, but rather are interdependent. As a result, their very low graphitization ability, resulting from the intrinsic nature of the PAN polymer and their small diameter, is closely related to the electrochemical properties of the resulting electrochemical devices.

7.2.4 Electrospun Porous Carbon Nanofibers

Porous carbon materials have attracted much attention because of their versatile applications in catalysis, sensors, electronic devices, gas or liquid separation, and storage [7.65–70]. The conventional process for the production of porous carbon materials requires a pore creation step (so-called activation), which involves complex chemical and physical phenomena occurring on multiple time and temperature scales and is also expensive [7.71]. Against this background, intensive studies have been carried out to identify controllable and cost-effective synthetic routes such as the template method and use of polymer blends. The template technique has been utilized as a powerful tool to control pore sizes exactly in the nano to macro range [7.72–74]. The alternative for obtaining porous carbon materials is melt-spinning of immiscible polymer blends with subsequent thermal treatment [7.75–77]. In recent years, electrospinning has been shown to be a simple but powerful technique for preparation of functional nanofibers with submicrometer diameter [7.78]. There have been a few reports on preparation of electrospun carbon nanofibers from pure PAN [7.79–84], because PAN is a well-known precursor for conventional micro-sized carbon fibers [7.1–3]. Also, synthesis of fibrous carbons with a single and continuous hollow core has been reported by different groups using melt-spinning [7.85] and the co-electrospinning [7.86] of immiscible polymer blends with subsequent thermal treatments.

Thus, it is possible to fabricate porous but nano-sized fibrous carbon materials in web form through nanofiber formation using the recently highlighted method of electrospinning of two immiscible polymer solutions and subsequent thermal treatment at 1000 °C in an inert atmosphere. Use of the electrospinning method enables production of nanosized (≈ 400 nm) organic fibers containing two separate

phases (sea and islands in cross-section) in web (or sheet) form, where the continuous phase (or sea) transforms into pore walls (or the skeleton of the nanofiber) and the discontinuous phase (or islands) forms multiple hollow pores that develop along the fiber length through thermal decomposition when thermally treated at 1000 °C.

Polymer blend solutions can be prepared by dissolving two or more different polymers in solvent, where phase separation into sea–island features occurs due to the intrinsic nature (e.g., interfacial tension, viscosity, elasticity) of the polymers [7.87]. Such stable emulsion-like polymer blend solutions are prepared by judicious selection of the two types of polymers, their blend ratios, and the solvent; the continuous phase (or sea) consists of PAN solution, and the homogeneously dispersed island-like phase consists of polymethylmethacrylate (PMMA) solution. Empirically, to understand the resulting morphological changes with the blend ratios and the nature of the constituent polymers, we have carried out viscosity and surface tension measurements for the polymer blends. All solutions showed shear-thinning behavior due to increasing orientation of drops along the flow direction at increasing shear rates. Also, the viscosity increased when the volume fraction of PAN in the blend solutions increased. Interestingly, we obtained lower surface tension for PAN solution (5.195 mN/m) than for PMMA solution (8.843 mN/m). Thus, the surface tension of our constituent polymers is thought to be the most important factor determining the cross-sectional morphology of the electrospun organic nanofibers. As a result, the low-surface-tension polymer (PAN) occupies the continuous phase (or sea) while the high-surface-tension polymer (PMMA) forms the discontinuous phase (or islands).

Thus, we were able to obtain homogeneous and long organic nanofibers in the form of a thin white web through use of optimized electrospinning conditions. The conversion of an organic nanofiber into a carbon nanofiber involves stabilization and thermal treatment steps. Air stabilization of electrospun nanofibers, which involves complex chemical reactions such as three-dimensional cross-linking, is accompanied by a change in color from white to reddish brown. Finally, by thermally treating the air-stabilized fibers, we obtain a black web consisting of fibrous carbon containing multiple hollow cores.

As shown in Fig. 7.19a–c, the electrospun organic nanofibers exhibit a smooth outer surface, a long fibrous morphology, and a homogeneous diameter distribution in the range 200–400 nm. The higher the fraction of

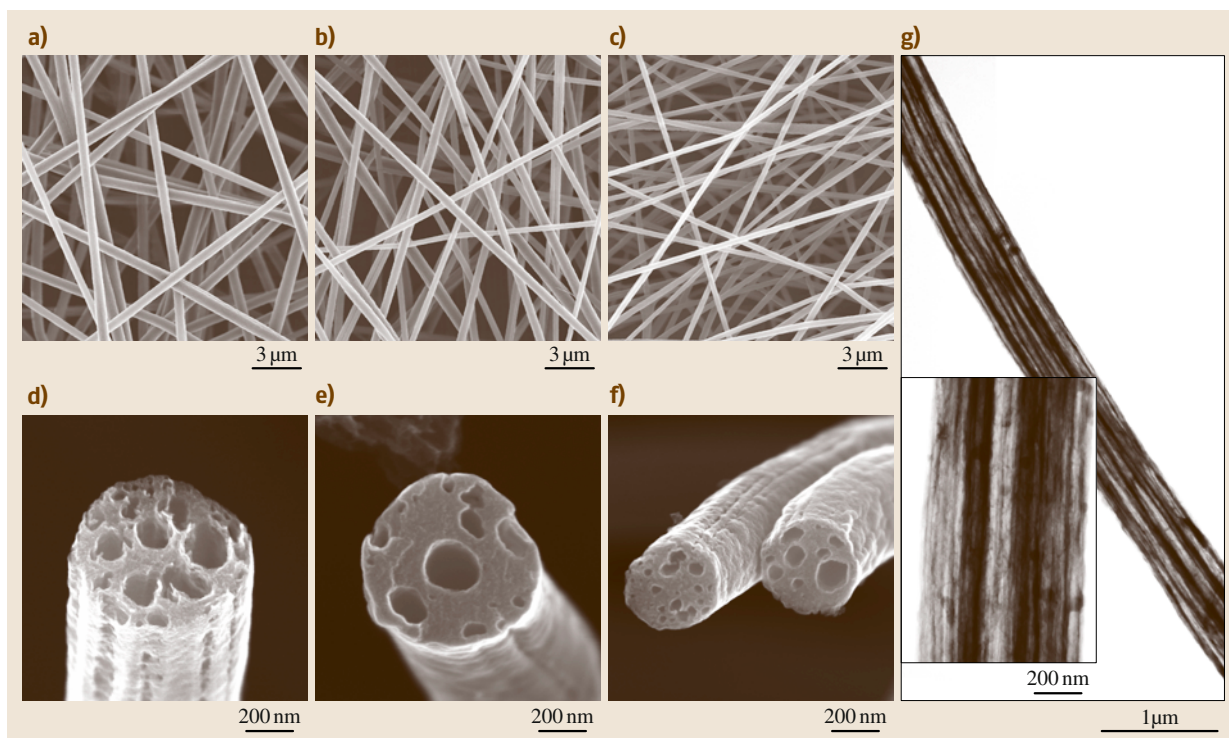

Fig. 7.19 (a–c) Macromorphologies of electrospun polymeric nanofibers containing two polymer phases (PAN/PMMA = (a) 5/5, (b) 7/3, and (c) 9/1), and cross-sectional FE-SEM images of nanofibers thermally treated at 1000 °C (PAN/PMMA = (d) 5/5, (e) 7/3, and (f) 9/1). (g) TEM image of the sample shown in (d) (PAN/PMMA = 5/5), showing linearly developed multiple hollow cores along the fiber length (*inset* shows a magnified TEM image)

PAN polymer, the smaller the diameter of the obtained nanofibers, basically due to their high ability to form fibers (or spinnability). Here it is noted that an electrospun organic single nanofiber consists of two phases, namely the discontinuous and long rod-like PMMA phase and the continuous PAN phase. Then, we carried out studies of the air stabilization of electrospun nanofiber web at 280 °C for 1 h under controlled air circulation, which is critical to sustain their fibrous morphology through the introduction of dimensional stability. Therefore, the fibrous morphology is not disrupted by the following thermal treatment step at 1000 °C in an inert atmosphere, as in the case of conventional PAN-based carbon fiber. Since the elongated PMMA phase decomposes (or disappears) without carbon residue and the continuous PAN phase was easily transformed into carbon ($\approx 40\text{--}50\%$) during thermal treatment, we successfully created multiple hollow cores within a single carbon fiber. As shown by the cross-sectional SEM images of carbon

fibers thermally treated at 1000 °C in Fig. 7.19d–f, multiple hollow cores were present in a single carbon fiber. Interestingly, the number of hollow cores increased with increasing PMMA concentration. In addition, low-resolution TEM images (Fig. 7.19g) indicated that the long but discontinuous multiple hollow cores are well developed along the fiber length. Thus, we are able to control the diameter, number, and length of hollow cores in a single carbon nanofiber using well-known polymer chemistry knowledge. Finally, the rugged surface morphology of the thermally treated carbon nanofibers (Fig. 7.19d–f) is believed to be the combined result of abrupt gas evolution of both polymers and also the carbon densification process. Therefore, it is expected that the blend ratio of the constituent polymers will greatly affect the patterns of pore creation as well as the porosity of the carbon nanofibers.

On detailed TEM study after thermal treatment at 2800 °C, the outer surface of all samples was

Fig. 7.20a–d Cross-sectional images of nanofibers thermally treated at 2800 °C (PAN/PMMA = (a) 5/5, (b) 7/3, and (c) 9/1); (d) TEM image of the sample shown in (a), showing multicore wall structurally developed through thermal treatment

transformed from relatively rugged to largely irregular because of the large changes in real density resulting from the high-temperature treatment. It is interesting to note that the multiple hollow cores in

a single fiber did not collapse (Fig. 7.20a–c) and that the pore walls/skeletons (≈ 10 nm), consisting of ca. 15 graphene sheets, were crystalline on the short range but undulated along the fiber length (Fig. 7.20d).

7.3 Applications of Carbon Nanofibers

The particular characteristics of carbon nanofibers due to their small dimension, excellent physico-chemical properties, and relatively low cost make them useful in versatile applications ranging from multifunctional composites, electrode materials for supercapacitors, anode electrodes or additives for lithium-ion batteries, supporting materials for metal particles, to bone tissue scaffolds. In this section, we present some of the important applications of carbon nanofibers.

7.3.1 Electrode Material in Lithium-Ion Secondary Batteries

Since sp^2 -based carbon materials were adopted as anode materials in commercialized lithium-ion batteries (LIBs) to solve safety problems, various types of carbon textures have been examined to improve the specific energy and power density of batteries [7.88–92]. The capacity as well as cyclic performance of LIBs strongly depend on the carbon texture due to the very different

lithium-ion (Li^+) insertion and desorption mechanisms. More recently, development of high-power LIBs has been required to meet growing demand for use in lighter electronic portable devices and hybrid electric vehicles (HEV). Thus, intensive study has been focused on nanosized carbon materials as promising materials for storing Li^+ , because they show increased capacity as an active material and also improved cyclic characteristics when used as an additive to anode and cathode materials [7.93–100].

Through the right combination of the electrospinning technique and thermal treatment process, dimensionally thin, mechanically tough, electrically conductive web-based electrodes consisting of interconnected nanofibers with a diameter in the range 200–300 nm have been fabricated. No binder or conductive filler (e.g., polyvinylidene fluoride, carbon black) was used in the fabrication of the active electrode, to enable evaluation of the anodic performance of the electrospun carbon nanofiber web. Therefore, the thin web in combination with their expected good mechanical and electrical properties makes them very attractive for fabrication of anode materials in thin polymer LIBs. Figure 7.21 shows voltage profiles for nanofiber webs thermally treated at 700 °C, 1000 °C, and 2800 °C. Even though carbon nanofibers thermally treated at 700 °C and 1000 °C have large Li^+ storage capacity of 510 and 1000 mAh/g, their reversible capacities are 300 and 450 mAh/g, respectively. Their large irreversible capacities (≈ 500 mAh/g) are closely related to electrolyte decomposition and the formation

of a solid electrolyte interphase at ≈ 0.8 V [7.101]. However, after the second cycle, relatively stable reversible capacity could be obtained. Nanofiber web thermally treated at 2800 °C exhibits a reproducible discharge/charge plateau at about 0.2 V (stage formation) and provides a reversible capacity of 130 mAh/g. As mentioned above, thermally treated PAN polymer could be characterized as a typical nongraphitic carbon, and thus has low discharge capacity due to its low crystallinity. It is noteworthy that carbon nanofibers thermally treated at 1000 °C have reversible capacity of 450 mAh/g, which is larger than both the theoretical value for graphite (372 mAh/g) and the value of 300 mAh/g for carbon nanofiber thermally treated at 700 °C.

Very recently, Yoon et al. [7.102] reported high capacity of 431 mAh/g for highly crystalline carbon nanofibers through the catalytic chemical vapor deposition method by carrying out a systematic study of the anodic behaviors of very different crystalline and textured carbon nanofibers. Also, relatively crystalline carbon nanofibers obtained by applying direct-current (DC) high voltage to a mist of 2-propanol showed a large reversible capacity of ≈ 340 mAh/g [7.103]. It is not clear why the reversible capacity of our carbon nanofiber thermally treated at 1000 °C exhibited the largest reversible capacity of 450 mAh/g as compared with various carbon nanofibers including microsized PAN carbon fiber (≈ 220 mAh/g) [7.104]. One possible explanation is that the nanosized fiber morphology invokes different carbonization behavior including gas

Fig. 7.21 Charge–discharge curves for nanofiber webs thermally treated at 700 °C, 1000 °C, and 2800 °C (current density 30 mA/g, second cycle)

Fig. 7.22 Variation of reversible capacities (rate capability) for nanofiber webs thermally treated at 700 °C, 1000 °C, and 2800 °C at different discharge current densities of 30, 50, and 100 mA/g ◀

evolution and pore development and thereby different surface properties when compared with microsized polymeric materials. In other words, the higher reversible capacity (up to 450 mAh/g) is expected to originate from the peculiar microtexture of carbon nanofibers thermally treated at 1000 °C, e.g., the highly disordered structure, defects, and dangling bonds. Thus, Li ions are inserted/deserted into and out of carbon nanofibers by a doping/dedoping process, because we could not observe any distinct redox peaks from the derivative voltage profiles (not shown here). This takes into account that a nanofiber web treated at low temperature (700 °C and 1000 °C) with constant and slightly inclined charge potential profiles is quite suitable for electronic portable device and HEV applications due to easy distinction of the the remaining battery capacity. In addition, when considering the battery rate capability (30, 50, and 100 mA/g) of samples thermally treated at 700 °C, 1000 °C, and 2800 °C (Fig. 7.22), there was no large degradation of capacity as a function of discharge current density compared with conventional graphite. In other words, this result confirms that the Li^+ diffusion path within anode materials is greatly reduced due to the small diameter of the carbon nanofibers.

7.3.2 Electrode Material for Supercapacitors

Supercapacitors have been intensively investigated as a main and/or backup energy storage systems, because they are able to carry high power and, furthermore, to have a long lifecycle [7.105]. Their double-layer ca-

pacitances strongly depend on the types and forms of the electrode materials. Against this background, various forms and textures of porous carbon have been examined as possible electrode materials for supercapacitors [7.106–111]. Among these, carbon nanotubes have attracted lots of attention, because they have large accessible surface area, based on their nanosized diameter, and relatively high electrical conductivity, which makes them very promising as efficient electrode materials for use in high-power supercapacitors [7.112–116]. Currently, their intrinsic problems, such as the limited amount of available charge and high cost, combined with their low effective specific surface area, limit practical use of carbon nanotubes as the electrode material in supercapacitors.

Another route to the fabrication of fibrous carbon as the electrode material for supercapacitors, based on electrospinning and subsequent steam activation, has been reported [7.33]. The preparation process involves fiber formation from a PAN polymer solution using electrostatic force. The technical reason for selecting PAN as a precursor was the good electrospinnability of PAN polymer solution and the relatively high carbon yield. The subsequent physical activation to increase the specific surface area or to create pores by subjecting air-stabilized carbon to steam at high temperature involves complex chemical and physical phenomena occurring on multiple time and temperature scales, and this step was known to be difficult in terms of controlling the pore size and surface properties of the obtained carbon materials, as well as being time consuming [7.117–119].

When considering their versatile promising applications in catalysis, electrochemical energy storage systems, and gas or liquid separation and storage, a simple and effective technique for decreasing the fiber diameter of ≈ 100 nm and also creating effective pores in a controllable fashion has to be developed to maximize the intrinsic 1-D functions (e.g., large accessible surface area and enhanced electrical and mechanical properties). Here we report a method for preparing porous, smaller-sized fibrous carbon in thin web form with the help of zinc chloride. Specifically, zinc chloride decreases the fiber diameter from 350 to 200 nm during electrospinning, enhances the reaction rate catalytically during air stabilization, and effectively creates suitable pores on the outer surface of smaller-sized (≈ 100 nm) carbon

nanofibers during thermal treatment. Also, dimensionally thin but flexible, an electrically conductive black web consisting of physically entangled, long carbon nanofibers enabled us to fabricate highly pure and self-sustained electrodes, without using binder or conductive materials; furthermore, the suitably developed micropores as well as the large external surface directly contributed to good capacitive behavior of supercapacitors.

The resultant black web, consisting of porous and long carbon nanofibers with diameter of 100 nm, was cut into a rectangular (2.25×2.25 cm) shape, and then attached to nickel plates to evaluate the capacitive performance based on a two-electrode system. The electrochemical properties of the carbon nanofiber web electrodes were studied by cyclic voltammetry in 6 M KOH aqueous solution as an electrolyte. Typical cyclic voltammograms (CVs) at 10–200 mV/s scan rate are shown in Fig. 7.23. The CVs were recorded in the potential range between 0 and 0.9 V, where no obvious redox peaks originating from the functional groups are observed. It is well known that CVs for an ideal double-layer capacitor are characterized by a perfectly rectangular-shaped profile [7.105]. For our samples, the CV profiles deviated from this ideal shape, but the shape of the curve is still satisfactory, even at the high scan rate used. However, the relatively broad feature in the CV of all samples could be considered as a side-reaction closely related to the intrinsic nitrogen functionalities derived from the parent PAN and also oxygen functional groups formed by zinc chloride.

When the zinc chloride was increased from 1% to 5%, the specific capacitances, calculated from CV

curves, increase from 120 to 140 F/g without any distinct changes in the shape of the CV profiles (Fig. 7.24a), indicating not only a reduction in the equivalent series resistance of the nanofiber web electrode, but also a reduction in the hindrance of ion penetration into the pores. The specific capacitance of our sample was higher than that of freestanding multi-walled carbon nanotubes in KOH medium (≈ 113 F/g) [7.112]. In addition, the samples showed relatively high rate capability (Fig. 7.24a). In other words, the sample exhibited good capacitive behavior with low diffusive limitation compared with conventional activated carbon materials, which could be explained by the highly intermingled porous nanofiber network providing an easily available electrode–electrolyte interface to form an electric double layer.

We measured the alternating-current (AC) impedance spectra (Nyquist plot) (Fig. 7.24b), because this technique enables one to distinguish the resistance and capacitance of devices. The impedances nearest to the origin were determined at high frequencies. This plot consists of three main regions (inset to Fig. 7.24b):

- (I) A semicircular arc representing the resistance and capacitance of the contact between the electrode and current collector, and the resistance of the porous electrode itself.
- (II) Another, small semicircular arc corresponding to the movement of electrons across the electrical double layer.
- (III) A (near-vertical) straight line at low frequency, suggesting blocking electrode behavior. This very

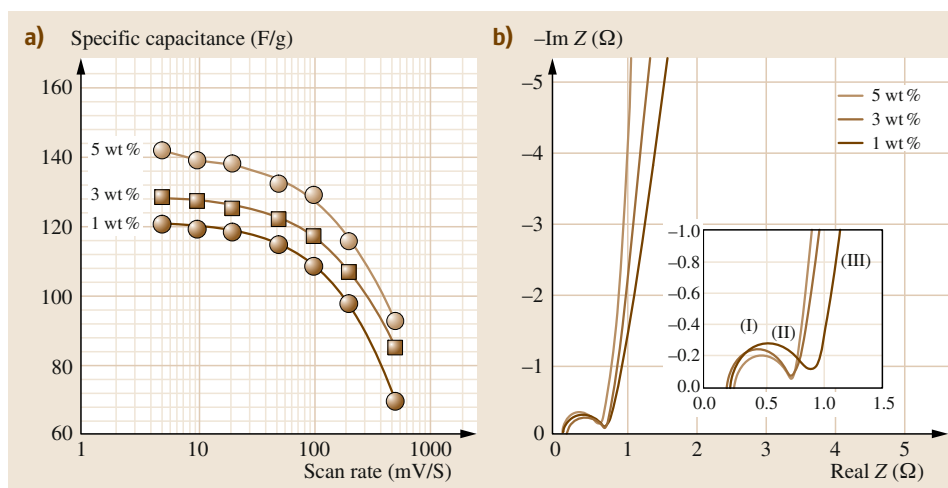

Fig. 7.24 (a) Gravimetric capacitances of all samples in 6 M KOH at different sweep rates, (b) complex-plane impedance plots of zinc-chloride-activated porous nanofiber-based electrodes (AC signal level 10 mV; frequency range 10 mHz to 100 kHz)

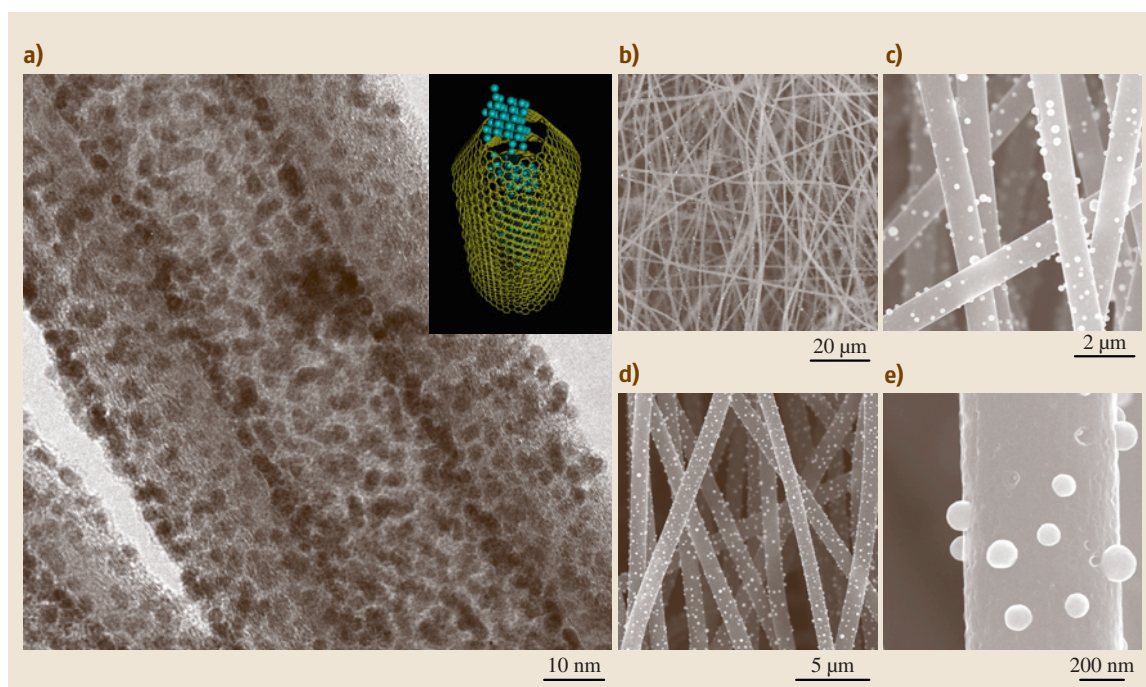

Fig. 7.25 (a) HRTEM image exhibiting high dispersion of Pt nanoparticles only on the surface of a carbon nanofiber. (b–e) SEM images of electrospun-based carbon nanofibers at different resolutions. Note that spherical palladium particles homogeneously cover the outer surface of the carbon nanofibers

steep spike shows that the kinetics of the diffusion of ions in the solution as well as the adsorption of ions onto the electrode surface occur swiftly. Therefore, the Warburg impedance, representing the diffusion of ions in pores and in the electrolyte, is unnoticeable.

The values I and II (inset of Fig. 7.24b) gradually decrease with increasing zinc chloride content from 1 wt % to 5 wt %, respectively. Electrolyte accessibility becomes greater for the larger pores, while the ions will not enter the smallest pores. Thus, lower resistance is associated with better electrolyte pore accessibility. In

the case of the sample with 5 wt % added zinc chloride, the pore density is higher than for the others, which is why the capacitive behavior appears at lower resistance.

7.3.3 Supporting Material for Metal Nanoparticles

For a decade, nanocarbon materials have been widely studied as catalyst supports for use in heterogeneous

catalysis due to their unique morphology and reactivity [7.120–122]. It is well known that the basic properties of impregnated catalyst are strongly affected by the impregnation method, microstructure, surface reactivity, and the metal precursor [7.123, 124]. Among these factors, appropriate morphology and nanostructure of the support is considered to be the main factor enabling the production of a well-dispersed nanoparticle catalyst as in Fig. 7.25.

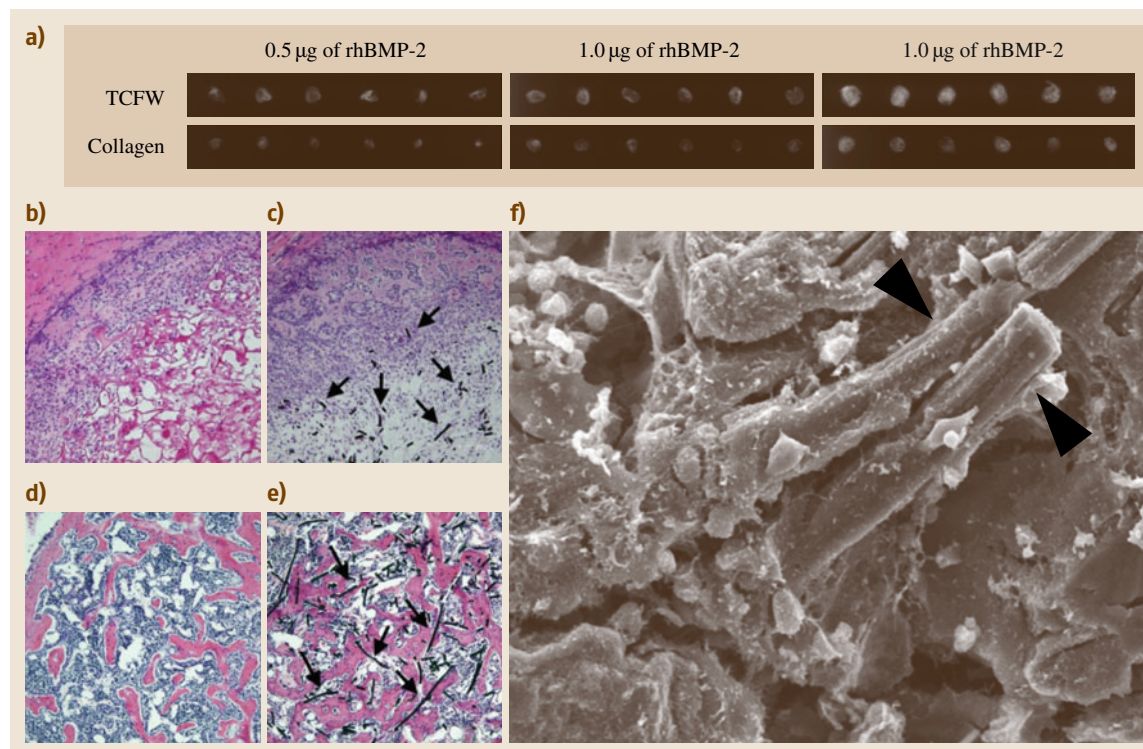

Fig. 7.26a–f Ectopic bone formation in the dorsal muscle of mice. **(a)** X-ray images of ectopic bone formed by rhBMP-2/carbon nanofiber web and rhBMP-2/collagen implants. Three weeks later, bone trabecular shadows were observed in all of the carbon nanofiber web and collagen implants with 0.5, 1 or 5 mg rhBMP-2. The bone trabecular shadows were clear and large and corresponded to the rhBMP-2 dosage in both groups. At each dose, the shadows of the carbon nanofiber web group were larger than those of the collagen group. **(b–e)** Bone formation of the carbon nanofiber web and collagen implants with 5 mg rhBMP-2. At 1 week, both the rhBMP-2/collagen **(b)** and rhBMP-2/carbon nanofiber web **(c)** showed the presence of immature bone matrix in the peripheral zone of the implants. The maturity of the collagen and carbon nanofiber web groups was the same. At 3 weeks, both the rhBMP-2/collagen **(d)** and rhBMP-2/carbon nanofiber web **(e)** specimens demonstrated normal-appearing bone with thick trabecular and hematopoietic marrow. Mature trabecular of the carbon nanofiber web group was thicker than in the collagen group. The collagen sheets were absorbed, but the carbon nanofibers remained and were in dense contact with the bone matrix. Hematoxylin and eosin staining. Scale bar: 200 mm. Arrows: carbon fibers. **(f)** SEM image of tissue sections containing the carbon nanofiber web with 5 mg rhBMP-2 at 3 weeks after operation. The carbon fibers were directly integrated into the new bone and adhered closely to the bone matrix with no intervening space. Scale bar: 10 mm. Arrow heads: carbon nanofibers

Efficient impregnation of Pt nanoparticles (outer diameter < 3 nm) into carbon nanofibers has been reported [7.125]. The method involves dispersion of the nanofibers in H_2PtCl_6 , followed by low-temperature annealing. The Pt particle deposition is homogeneous, and can be controlled selectively on the outer or internal core using the hydrophobic nature of the material (Fig. 7.25a). Since the activity of the Pt nanoparticles on the fibers is high, this material could find application in efficient catalysts and allied biological devices. Alternatively, carbon nanofibers containing palladium nanoparticles have been prepared simply by electrospinning polymer solution containing palladium chloride and subsequent thermal treatment in argon [7.126]. It has been demonstrated that palladium oxide formed during air stabilization transforms into nanoparticles through an interaction with the carbon material. Since the palladium nanoparticles homogeneously covering the outer surface of the nanofibers (Fig. 7.25b–e) are small enough to have high catalytic activity, this material could find application in efficient catalysts and hydrogen sensors.

7.3.4 Bone Tissue Scaffold

At present, the most popular scaffold is type I collagen [7.127–129], which is often used in clinical applications [7.130, 131]. However, use of collagen leads to certain problems such as the possibility of disease transfer or immunogenic reactions due to xenogenicity [7.132–134]. Further, the soft nature of collagen does not allow it to preserve its shape in the

body. Actually, carbon fibers have been used for tendon repair in clinical settings [7.135, 136], but they are too thick for use in cell or cytokine therapy for tissue regeneration. If creation of a three-dimensional web consisting of carbon fibers with a nanostructure is possible, it may serve as a promising new scaffold biomaterial for tissue regeneration. Thus, by using the electrospinning method, a carbon nanofiber web consisting of high-purity carbon was examined as a bone tissue scaffold [7.35]. The carbon nanofiber web consists of high-purity carbon with a very small amount of functional groups. It is considered to be safe in the living body even when present at high levels. In vivo implantation for a short time period resulted in little inflammatory reaction of the surrounding tissue, indicating that this material is highly biocompatible. Examination of the interface between the carbon fibers and bone matrix by using FE-SEM revealed that the carbon fibers directly adhered to the bone itself without any intervening space being integrated into the bone matrix, indicating high bone tissue compatibility. Recombinant human bone morphogenic protein-2 (rhBMP-2)/nanofiber web composite implants could induce ectopic new bone formation effectively when tested in vivo and could repair large bone defects orthotopically (Fig. 7.26). It is envisaged that the nanofiber web is a promising scaffold material candidate for use in bone regeneration therapy and represents a prominent advance in technology for enhancement of bone repair. We also expect that such carbon-nanofiber-derived scaffold systems will play a major role in regeneration therapy for various tissues in future clinical applications.

7.4 Conclusions

The 19th century can be remembered as the iron age, while the 20th century is recognized as being founded on silicon technology. Now, much attention is being paid to fibrous nanocarbon materials as one of the promising candidates that could revolutionize technology in the 21st century. Carbon nanofibers differ from conventional carbon fibers in their nanosized diameter and from carbon nanotubes in their intrinsic geometry. Thus, they could be visualized as connecting bridges between molecular and macro materials. However, some

challenges have to be solved in order to speed up industrial use of carbon nanofibers. The first challenge is large-scale synthesis of defect-free carbon nanofibers at low cost. Secondly, it is important to control the diameter and length of carbon nanofibers. The final and most important challenge is how to manipulate (or disperse) such nanosized entangled fluffy materials in order to fabricate novel multifunctional materials. It is envisaged that various carbon-nanofiber-based products will be seen in less than 10 years.

Nanodiamond

8. Nanodiamonds

Olga A. Shenderova, Suzanne A. Ciftan Hens

This chapter presents a brief survey of the different classes of nanodiamond particles and a comparison of their purity, structure, and physical properties. The primary focus of this chapter is on nanodiamond particles produced by detonation shock wave-assisted synthesis, thus harnessing the energy of explosives. Selected applications of nanodiamond particles are discussed, including for polishing, as a filler material for nanocomposites, in drug delivery, and for chemical vapor deposition of diamond films.

Nanostructured diamond particles were first synthesized at the beginning of the 1960s using the energy of explosives. Diamond powders in the form of micrometer-sized single particles with nanocrystalline structure were produced using shock wave compression of carbon materials (graphite, carbon black) mixed with catalyst by *DeCarli* and *Jamieson* [8.1]. The size of the primary grains in the polycrystalline particles was about 10–20 nm. The product has been commercially available since the 1970s and since then has been widely used in the polishing industry. An alternative approach for producing diamond powder with a characteristic size of primary particles of $\approx 4\text{--}5$ nm, from the carbon contained in high-energy explosives themselves, was invented in the former USSR [8.2], but this material remained essentially unknown to the rest of the world until the end of the 1980s [8.3]. While these so-

called detonation nanodiamonds (**DND**) have diameters of 4–5 nm, they tend to aggregate, and typical commercial suspensions of **DND** contain larger aggregates, up to several hundred nanometers in size (which can withstand ultrasonic treatment). While **DND** was produced in quantities by the tons in the former USSR, the material did not penetrate the world market. Nanodiamond particles have become an object of keen scientific interest all over the world only within the last 5–6 years. The reason for this is fourfold. First, colloidal suspensions of individual nanodiamond particles of only 4–5 nm in size (so-called single-digit nanodiamond) recently became available [8.4]. Second, the production of nanodiamond particles containing specific impurity defects that allow for photoluminescent particles seems poised to revolutionize biological imaging and quantum optics applications [8.5, 6]. Third, the chemical reactivity of

the nanodiamond (ND) surface that allows it to participate in a wide range of chemical reactions and its ability to easily modify surface chemical groups [8.7] permit NDs to be readily used in many applications. Fourth, ND is reported to have the lowest toxicity among all known carbon nanoparticles [8.8, 9].

The availability of single-digit ND particles produced by detonation of explosives in kilogram quantities has opened broad prospective applications of NDs in composites and nanolubricants, and as drug delivery vehicles. Indeed, the specific surface area of ND particles with 4 and 30 nm diameter is 428 and 57 m²/g, respectively, making a noticeable sevenfold difference in the adsorbing and loading capacity of the nanoparticles. The availability of single-digit ND particles is also important for biomedical applications for delivery of biologically active molecules, for example, through the blood–brain barrier [8.10].

A central focus of many research groups remains the controlled production of nitrogen-vacancy (NV) centers in nanoscale diamond. Due to the strong optical transition, single defects can be detected using a fluorescence microscope. The spin state of the negatively charged NV centers can be polarized by optical pumping and can be manipulated using electron paramagnetic resonance (EPR), permitting the implementation of efficient single-photon emitters for quantum information processing [8.5] or magnetic sensors with nanoscale resolution [8.6]. Single color centers show outstandingly high photostability, even at room temperature [8.11]. Bright photoluminescent NDs were produced using high-pressure high-temperature (HPHT) diamond, containing 10–300 ppm of native substitutional nitrogen defects (N_s), ground to nanosized particles [8.11, 12], and irradiated with en-

ergetic particles (electrons, protons, etc.) to create vacancies.

The two major breakthroughs, i.e., production of nanodiamond particles 4–5 nm in size and nanodiamond particles containing impurity defects exhibiting stable luminescence and unique spin properties, are related to nanodiamond particles synthesized by different techniques: detonation of explosives and grinding of HPHT diamond, respectively. Thus, these two important characteristics are not available through a single synthesis route. Synthesis of NDs a few nanometers in size with specific color centers remains elusive.

For a newcomer to the field, there is a baffling array of types of nanodiamond particles available for research. Besides the detonation of explosives technique, diamond with characteristic sizes encompassing several nanometers has also been synthesized by other methods, particularly by chlorination of carbides [8.13], ion irradiation of graphite [8.14], electron irradiation of carbon onions [8.15], laser ablation of carbon precursors [8.16], and in the vapor phase in a substrate-free low-pressure microwave-plasma chemical vapor deposition (CVD) reactor [8.17]. Moreover, astronomical observations suggest that nanodiamonds are present in the protoplanetary disks of certain types of stars [8.18, 19]. The origins of these cosmic sources are still under investigation.

A central goal of this chapter is to present a brief survey of the different classes of nanodiamond particles and provide a comparison of their purity, structure, and physical properties. Another purpose of the chapter is to review applications where unique properties of ND particles provide significant benefits, such as biomedical applications, nanocomposites, and as seeding material for growth of diamond films.

8.1 Stability of Diamond at the Nanoscale

It is well known that graphite is the most stable form of carbon at ambient temperatures and pressures, and that diamond is metastable. The energy difference between the two phases is only 0.02 eV/atom. However, because of the high activation barrier for the phase transition (≈ 0.4 eV/atom), very high temperatures and pressures and/or the use of a catalyst are required to realize the phase transformation. At the nanoscale, however, the carbon phase diagram must also include cluster size as a third parameter (in addition to pressure and temperature) because the Gibbs free energy depends on the surface energy, which leads

to changes in the phase diagram [8.20, 21] (Fig. 8.1). The authors [8.20] report better agreement with calculations for experimental shock pressure–volume and temperature data using a *nanocarbon phase diagram* than those obtained with a bulk carbon equation of state. The results also suggest that carbon particles, of the order of 10³–10⁴ atoms, can exist in the liquid state at lower temperatures than bulk carbon (Fig. 8.1). Danilenko [8.21] applied the phase diagram for the nanocarbon phases to a detailed elaboration of the mechanism of DND formation, which is described in a later section. Chevrot et al. [8.22] performed

Fig. 8.1 Phase diagrams for bulk and nanoscale (blue lines) carbon. Red lines demonstrate a pressure–temperature trajectory in a detonation wave during synthesis of detonation nanodiamond (for the composition RDX/TNT 64%/36%). A corresponds to the shock compression of the explosives (chemical peak), AB corresponds to decomposition of explosive molecules, and B is the termination of decomposition (the Jouguet point) (after [8.21])

a molecular dynamics study of carbon nanoparticles of different sizes in sp^2 and sp^3 starting configurations under high-temperature (1000–7000 K) and high-pressure (2–45 GPa) conditions. For finite-size clusters, the transition line between the graphite and the diamond structure was shifted to higher pressures as the size of the cluster decreased, supporting the findings by Viecelli et al. and Danilenko.

The relative phase stability of carbon nanoparticles has been a focus of numerous theoretical and computational studies. First, *Badziag* et al. [8.23] using simple atomistic models predicted that, between 3 and 6 nm, diamond clusters become more stable than their graphitic counterparts. Later it was discovered that morphology plays a very important role in cluster stability in terms of surface reconstructions and appearance of sp^2 carbon fragments [8.24–27]. While the bare (nonfunctionalized) surfaces of cubic crystals exhibit structures similar to bulk diamond, the surfaces of octahedral, cuboctahedral, and spherical clusters show a transition from sp^3 to sp^2 bonding. The preferential exfoliation of the (111) surfaces begins for clusters in the subnanometer size range and promotes the cluster transition to endo-fullerenes for small clusters (\approx tens of atoms) and onion-like shells with diamond cores

(bucky-diamond) for larger clusters [8.25]. Large ND clusters (\approx 1–3.3 nm) of various shapes with less than 76% surface graphitization are likely to be stable in the diamond structure, possessing a thin (either single- or double-layer) graphitic shell [8.28]. Importantly, the simulations imply a strong correlation between structure, shape, and the sign of electrostatic potential, with bare carbon (100) surfaces exhibiting a positive electrostatic potential, and significant regions of (111) surface graphitization exhibiting a negative electrostatic potential. These theoretical findings imply that bare ND particles with reconstructed surfaces will be prone to aggregation due to electrostatic interactions between particles (assuming that the ND particles have no surface functional groups).

Barnard et al., analyzing carbon structures, identified two important size regimes, where sp^2 to sp^3 or sp^3 to sp^2 phase transitions may be readily expected [8.29]. As the system size for the carbon particles is increased, the most stable carbon form at the nanoscale changes from fullerene to onions to bucky-diamond to nanodiamond to graphite. For smaller particles the crossover between fullerene particles and nanodiamond may be expected at 1.5–2 nm, and for larger particles, the crossover in stability between nanodiamond and nanographite may be expected at around 5–10 nm in diameter.

The surface of sp^3 clusters must be either stabilized via termination with some functional groups or reconstructed into sp^2 carbon. Therefore, in addition to size and shape, the stability of carbon nanoparticles also depends on their surface terminations. *Raty* and *Galli* [8.30] used first-principles calculations to examine the relative stability of nanodiamond as a function of hydrogen coverage for different particle sizes. Their results indicated that, when the size of diamond is about 3 nm and larger, bucky-diamonds (Fig. 8.2a) are energetically preferred over hydrogenated nanodiamonds. Hydrogen-terminated nanodiamonds with sizes $<$ 1.5 nm (known as diamondoids) are stable molecules that occur naturally in oil [8.31].

First results of modeling of nanodiamonds terminated with oxygen [8.32] and nitrogen-containing functional groups [8.33] showed complex behavior where different groups favored different nanodiamond facets depending upon the temperature, the environment of the particle, as well as the size and morphology of the nanodiamonds.

Currently, different structural models of nanodiamond particles have been suggested for detonation ND (Fig. 8.2). In the earliest models, the diamond nanoclus-

Fig. 8.2a,b Structural models of nanodiamond clusters. Bare surface of diamond clusters experiences surface reconstruction resulting in a cluster with a diamond core and a fullerene-like shell: bucky-diamond (a). Red-colored atoms are sp^2 carbon atoms. Schematic model illustrating the structure of a single ≈ 5 nm nanodiamond after oxidative purification (b). The diamond core is covered by a layer of surface functional groups which stabilize the particle by terminating the dangling bonds. The surface can also be stabilized by the conversion of sp^3 carbon to sp^2 carbon (shown in black). ((a) Courtesy of G. Galli, Lawrence Livermore National Laboratory. (b) Courtesy of V. Mochalin, Drexel University)

ter was considered to consist of a crystalline diamond core coated by an onion-like carbon or amorphous carbon shell (core-shell model) [8.34, 35]. The models were derived based on experimental data obtained from x-ray diffraction and small-angle x-ray scattering of DND of different levels of purification. Later models suggested the presence of an intermediate layer between the perfect nanodiamond core and the sp^2 shell, resulting in a three-layer model of DND particles [8.36–38]. However, these models did not take into account surface functional groups present on DND due to different oxidation treatments of detonation soot [8.38, 39]. In the latest core-shell model it is considered that carbon atoms with dangling bonds on the outer surface are bonded to functional groups [8.40]. Additional characteristic features of the DND not included in the model are nitrogen impurities (up to 2–3 wt %) which can form complexes in the core of DND particles [8.41, 42] and the presence of twins and grain boundaries in the crystallites (Fig. 8.3b). The latter can be responsible for the broadening of the x-ray diffraction peaks earlier attributed to disordered sp^3 carbon.

Fig. 8.3a–f HRTEM images of a polyhedral particle of detonation nanodiamond (DND) (a). A faceted DND made up of a highly ordered diamond core (the inset with a fast Fourier transform of the micrograph confirms this) (b). Nanodiamonds synthesized by pulsed laser irradiation. A single-crystal structure (c) and multiply twinning structure (d). A spherical diamond in a carbide matrix synthesized by carbide chlorination process (e). A spherical HPHT ND particle obtained by high-energy ball-milling (f) (after (a) [8.43]; (c,d) [8.41, 44]; (e) [8.45]; (f) [8.12]) ▶

The DND models which originated from the experimental observations listed above assumed a spherical shape of DND particles, based on the earliest low-resolution transmission electron microscopy (TEM) observations of aggregates of DND [8.46]. Graphiti-

zation of the DND surface that might be initiated by the high-energy electron beam during TEM observations [8.47] also contributes to the impression of the ND particles having spherical shapes. However, using a nondestructive high-vacuum aberration-corrected electron microscope, *Iakubovskii* et al. demonstrated that DND grains could have crystalline structure with negligible fractions of nondiamond carbon [8.47]. These findings are consistent with earlier reports by *Tyler* et al. [8.43, 48] on clear diamond facets of individual polyhedral DND particles obtained by electrodeposition of ozone-purified DND on Mo tips [8.43] (Fig. 8.3a). Recently, *Turner* confirmed the absence of sp^2 carbon phase on small fractions of ozone-purified DND (Fig. 8.3b).

The survey of the existing DND models indicates that currently there is still no full agreement on the DND structure. Since the authors have studied differently synthesized and processed DND particles, it is quite possible that a single model cannot describe all kinds of NDs, and probably different models should be applied depending on the manufacturing and purification methods. Nevertheless, a model illustrating the most common and important features, suggested by

Mochalin et al., is illustrated in Fig. 8.2b. This model includes an almost perfect crystalline structure of the diamond grain, the presence of surface functional groups and their variability, the presence of sp^2 carbon (sometimes negligible fraction), and spherical or polyhedral shape of the particle.

Nanodiamond particles produced by other methods also have specific features; For example, *Hu* et al. [8.44] reported that, for nanodiamonds synthesized by pulsed laser irradiation, a preferred structure for smaller particles is a single-crystal structure (Fig. 8.3c), while for larger particles a multiply twinning structure was observed (Fig. 8.3d). The authors conclude, based on thermodynamic calculation, that the multiply twinning structure is more stable than the single-crystal structure in a certain size range. *Welz* et al. reported spherical shapes of nanodiamond particles in a carbide matrix synthesized by the carbide chlorination process [8.45] (Fig. 8.3e). Figure 8.3f demonstrates a spherical, free of sp^2 carbon particle of HPHT ND ground by high-energy ball-milling to the sub-10 nm size range [8.12]. Thus, ND shape and composition to a large extent depend on the method of synthesis and postsynthesis processing.

8.2 Types of Nanodiamonds and Methods of Nanodiamond Synthesis

Diamond structures at the nanoscale (the length scale of approximately 1–100 nm) include pure-phase diamond films, diamond particles, recently fabricated one-dimensional (1-D) diamond nanorods, and two-dimensional (2-D) diamond nanoplatelets. Nanoscale diamond structures of different dimensions have been reviewed in several publications [8.48, 49]. A focus of the current chapter is zero-dimensional nanodiamond, e.g., nanoparticles.

ND particles can be conveniently categorized into three groups according to the size of their primary particles (Fig. 8.4): nanocrystalline particles, ultrananocrystalline particles, and diamondoids. Characteristic sizes of nanocrystalline particles encompass the size range of tens of nanometers, while sizes of primary particles of ultrananocrystalline diamond are within several nanometers [8.49]. Diamondoids are well-defined hydrogen-terminated molecular forms consisting of several tens of carbon atoms with characteristic sizes ≈ 1 –2 nm [8.31]. While a choice of 10 nm as the margin between two classes of nanodiamonds

seems arbitrary, it reflects a difference in properties of the resulting products using diamond nanoparticles of different sizes. As pointed out in the Introduction, the specific surface areas of ND particles with 4 and 30 nm diameter make a noticeable sevenfold difference in the adsorbing and loading capacity of the nanoparticles. The term “single-digit ND” coined by *Osawa* [8.4] seems to be gaining broader acceptance in the community for sub-10 nm ND particles, rather than *ultrananocrystalline* ND particles.

The class of nanocrystalline diamond particles includes subgroups of monocrystalline and polycrystalline particles (Fig. 8.4). Monocrystalline nanoparticles include ND particles processed from HPHT synthetic diamond as well as from natural diamond powders, commercially available with smallest average particle size around 20 nm (produced, for example, by Microdiamant AG). Polycrystalline nanodiamond powder is processed from micrometer-sized polycrystalline diamond particles obtained by shock compression of graphite mixed with metals [8.1] (DuPont de Nemours’s

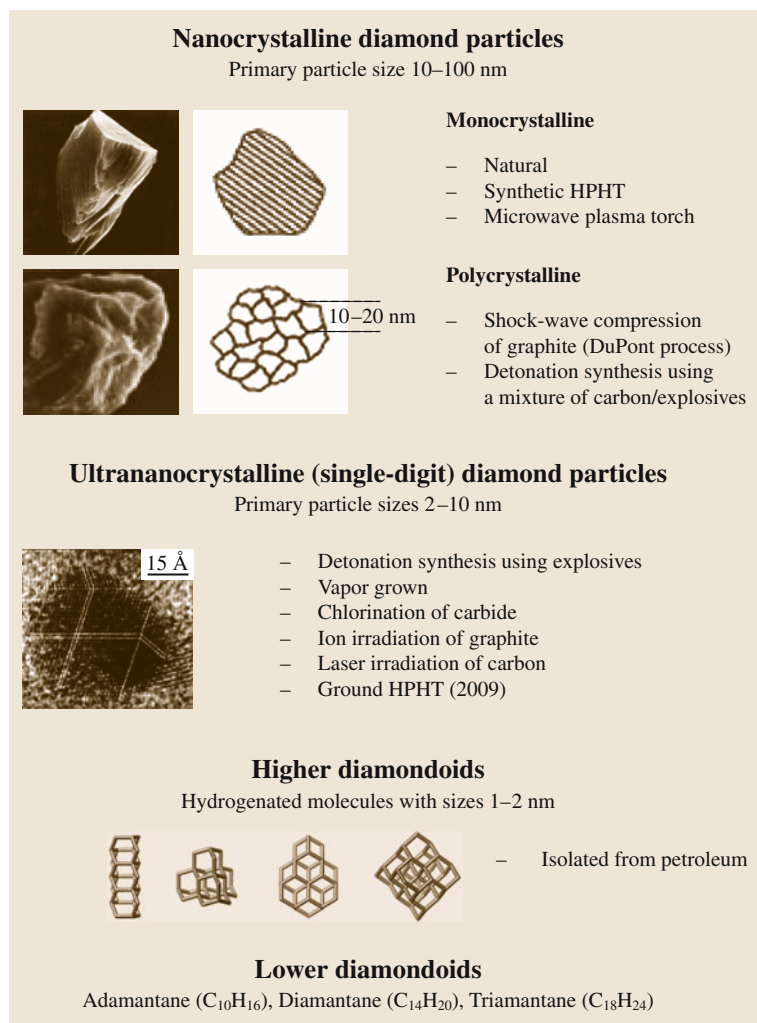

Fig. 8.4 Summary of the types of nanoscale diamond particles and molecular forms (low diamondoids) according to the primary particle size. (Pictures of nanocrystalline diamond courtesy of Microdiamant AG, Switzerland. Pictures of UNCD single particles courtesy of T.L. Daulton, Naval Research Laboratory.) Examples of higher diamondoids from petroleum, 1–2 nm hydrogen-terminated diamond molecules (*left to right*): rod-shaped [1212]pentamantane C₂₆H₃₂, pyramid-shaped [1(2,3)4]pentamantane C₂₆H₃₂, irregular disc-shaped [121321]heptamantane C₃₀H₃₄, octahedral [1231241(2)3]decamantane C₃₅H₃₆ (courtesy of ChevronTexaco MolecularDiamond Technologies)

method) or by detonation of a mixture of graphite and explosives (Tacii). Polycrystalline particles consist of nanometer-sized diamond grains ($\approx 10\text{--}20\text{ nm}$). The finest diamond fraction produced by micronizing followed by grading has an average size of an individual particle of $\approx 25\text{ nm}$ (Microdiamant AG).

Out of several types of ultrananocrystalline diamond particles (Fig. 8.4), only detonation ND, obtained by the detonation of solid explosives in an inert atmosphere, has been commercialized on a large scale. The average size of primary detonation ND particles produced by most vendors lies in the range of 3.5–6 nm. Recently, single-digit nanodiamond produced by laser ablation of carbon precursors has become commercially available (Ray Technologies). Details on the methods of syn-

thesis of other single-digit nanodiamond particles are provided in the next section.

Higher diamondoids (Fig. 8.4) are highly rigid, well-defined hydrogen-terminated diamond species [8.31, 50]. With more than three crystal diamond cages, higher diamondoids are intermediate in size to the adamantane molecule, the smallest species of H-terminated cubic diamond containing only 10 carbon atoms, and ultrananocrystalline diamond particles with sizes more than 3 nm as described above. Higher diamondoids are extracted from petroleum as diamond molecules in the form of nanometer-sized rods, helices, discs, pyramids, etc. [8.31, 51]. So far it has not been possible to synthesize higher diamondoids except anti-tetramantane, a tetramantane isomer [8.50]. By comparison, lower diamon-

doids (adamantane, diadamantane and triadamantane), extracted from crude oil much earlier than larger members of the diamondoid series, are currently available in kilogram quantities [8.50] and can be synthesized.

Figure 8.5 summarizes commercially available ND particles based on their method of synthesis. Major classes of commercial ND are those made by *static* and *dynamic* synthesis. While ND made by static synthesis is 1–2 orders of magnitude more expensive than ND made by dynamic synthesis, this material is a primary material for production of photoluminescent ND particles. ND made by static synthesis can be HPHT ND type Ib, with substitutional nitrogen (N_s) concentration 1–300 ppm. ND produced from natural diamond type Ia (N_s concentration up to 3000 ppm) is also available. Irradiation by high-energy particles of type Ib ND causes formation of NV centers with red emission, while ND from diamond Ia demonstrates green luminescence originating from the formation of N–V–N centers after irradiation and annealing. A large subgroup of nanodiamond is produced via *dynamic synthesis*, harnessing the energy of explosives and different carbon-containing precursor materials. Three classes of dynamically synthesized NDs are manufactured on an industrial scale (Fig. 8.6):

1. NDs produced by direct phase transformation of graphite induced by an external shock wave (the DuPont method) [8.1].

2. NDs produced from a mixture of a carbon precursor and explosives [8.52].
3. NDs produced from the carbon contained in high-energy explosives (so-called detonation ND (DND), or ultradispersed diamond [8.53, 54]. Such explosive compounds simultaneously serve as sources of energy and carbon.

Depending on the precursor material used in dynamic synthesis, NDs with primary crystal sizes between 4 and 25 nm can be synthesized. Slurries of 4 nm individual DND particles or slurries of polycrystalline NDs synthesized from graphite and graphite/hexogen precursors with average aggregate size of 20–30 nm are commercially available.

While the first publications on laser irradiation of graphite precursors in liquids appeared a decade ago [8.16], ND produced using a laser became commercially available (in small quantities) only recently (Ray Technologies Inc.). Primary particle size, as reported by the vendor, ranges between 2 and 10 nm. Aggregate size in water suspensions is about 100 nm. At the moment, this type of ND is two orders of magnitude more expensive than detonation ND.

Sections below provide more details on manufacturing of ND by dynamic synthesis, followed by a brief survey of methods of synthesis of ND particles produced on laboratory scale.

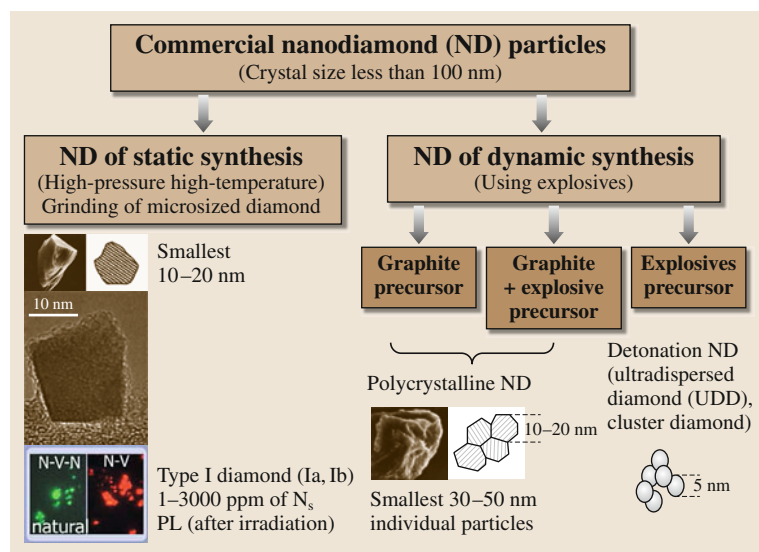

Fig. 8.5 Summary of types of commercial nanodiamonds (PL – photoluminescent)

Fig. 8.6 Classes of nanodiamonds produced by detonation shock wave-assisted synthesis on an industrial scale

8.2.1 Nanodiamond Produced by Detonation Shock Wave-Assisted Synthesis

Below, we briefly survey methods of synthesis and characteristics (crystal size, morphology) of the three classes of dynamically synthesized NDs manufactured on industrial scale (Fig. 8.6).

Nanodiamond Produced by Shock Conversion of Graphite

Synthesis of polycrystalline diamond particles produced by direct phase transformation of graphite induced by an *external* plain shock wave was first reported by DeCarli and Jamieson [8.1] and patented by DeCarli [8.55]. A patent by Cowan et al. (1968, assigned to DuPont de Nemours Co.) provided a means for significant increase of diamond yield during shock wave transformation of graphite by mixing graphite with cooling media. In 1976, this technology was commercialized by DuPont, producing microcrystalline diamond powder under the tradename Mypolex [8.56]. In parallel, studies of the formation of diamond in shock-loaded graphite were taking place in the former USSR at the VNIITF Institute (Snezhinsk) [8.56]. Dia-

mond production by the shock synthesis technique in spherical and cylindrical enclosures was first demonstrated in 1962 (2% diamond yield), followed by experiments with mixtures of graphite or soot with metals, resulting in 20% yield of diamond product (1963) [8.2, 56].

More specifically, under suitable conditions, explosively produced shock waves can create high-pressure ($\approx 20\text{--}200$ GPa), high-temperature (> 2000 K) conditions in confined volumes (Fig. 8.6) for a sufficient duration to achieve partial conversion of graphite into nanometer-sized diamond grains (≈ 20 nm); these grains compact into micrometer-sized, polycrystalline particles. Copper is mixed with graphite in this process to provide fast heat dissipation at the high temperatures reached during the explosion, which will avoid transformation of the diamond back to graphite [8.57]. Diamond powder with characteristic sizes of particles in the submicrometer range can be processed from micrometer-sized polycrystalline diamond particles obtained by shock synthesis. Polycrystalline diamond particles are tougher than monocrystalline diamond microparticles (natural or produced by HPHT) and are widely used in fine polishing applications. It is important to note that agglomerate-free suspensions of

nanocrystalline diamond particles (for both monocrystalline and polycrystalline forms) in water and oil are commercially available (Microdiamant AG, Lengwil, Switzerland).

Nanodiamond Produced from Carbon Precursor/Explosive Mixture

NDs produced by another dynamic method, detonation of a mixture of a carbon precursor (graphite or carbon black) and explosives, is much less well known in the community. This approach was invented at the Institute of Problems of Chemical Physics, Russian Academy of Sciences, Chernogolovka [8.58] and registered under the trademark DALAN (the Russian acronym for detonation diamonds of the Academy of Sciences). *Tat-sii* [8.52] summarized the data on the production of DALAN ND from three types of precursors: mixture of hexagen (RDX) and carbon black (charge density 1.34–1.39 g/cm³), RDX and graphite (charge density 1.61–1.67 g/cm³), and gunpowder/carbon/RDX (charge density 1.67–1.75 g/cm³). The concentration of carbon precursor materials can be varied between 5 and 35%. The detonation pressure measured by dynamic methods (in the Chapman–Jouguet plane) was about 27.5–14.5 GPa. It was concluded that the diamond powders synthesized from graphite consist of 1–3 μm particles of lamellar shape with different phase compositions (diamond, lonsdaleite, and graphite) and grain sizes. The particles of diamond powder synthesized from carbon black are aggregates consisting of 20–80 nm grains of cubic-phase diamond exhibiting either round or polyhedral shape. The particles of diamond extracted from the solid detonation products of the gunpowder/carbon black/RDX mixture are single-phase particles having homogeneous grain structure with grain size of mainly 1–3 nm. These smaller grains form spherule-shaped aggregates. These findings demonstrate the key role of the carbon precursor material in the phase composition and the primary particle size of the resulting products. Currently, polycrystalline diamond produced from graphite/RDX mixture is a valuable commercial product for polishing applications. While micrometer-sized particles (1–10 μm) with narrow size distribution are in greatest demand, the fractions of polycrystalline diamond with sub-100 nm particle sizes are also utilized.

Nanodiamond Produced from High-Energy Explosives

A method of production of ND from the carbon contained in high-energy explosives (detonation ND) was

developed in the former USSR in the 1960s [8.2]. The conversion of the carbon-containing explosive compounds into diamond occurs by firing the explosives in a detonation chamber [8.53]. The resultant product is a mixture of diamond particles with primary particle size of 4–5 nm, other carbon allotropes, and metallic impurities. A wide variety of explosive materials may be used. A typical explosive mixture is 2-methyl-1,3,5-trinitrobenzene (TNT) and hexogen (in the proportion 40 : 60) composed of C, N, O, and H with a negative oxygen balance, so that free nonoxidized carbon is present in the system. The explosion takes place in an inert medium of either gas (N₂, CO₂, Ar, or another medium that can be under pressure) or water (ice), called *dry* or *wet* synthesis, respectively. The medium acts as a coolant.

The product of detonation synthesis, called detonation soot or diamond blend, contains 40–80 wt % diamond phase depending on the detonation conditions [8.54]. The carbon yield is 4–10% of the weight of the explosive charge, depending on the cooling media.

Danilenko proposed the mechanism of nanodiamond formation during detonation [8.21, 56, 59]. The initial shock wave created by a detonator compresses the high-explosive material, heating it and causing chemical decomposition, thereby releasing enormous amounts of energy in a fraction of a microsecond. The detonation wave includes (Fig. 8.7) a shock wave, a zone of detonation-induced decomposition of ex-

Fig. 8.7 Schematic of the detonation wave propagation and formation of detonation nanodiamonds from nanocarbon droplets (as described in [8.21]) (courtesy of V. Mochalin, Drexel University)

plosive molecules (a zone of chemical reaction), and a zone of expanding detonation products. The zones of chemical reaction and expanding detonation products are shown for the so-called composition B explosive in the corresponding phase diagram (Fig. 8.1, red lines) [8.21]. Decomposition of explosive molecules with the formation of free carbon (for an explosive with negative oxygen balance) proceeds according to

In Fig. 8.1, point B corresponds to the termination of the decomposition (the Jouguet point). It can be seen in Fig. 8.1 that the P – T values at the Jouguet point do not reach the region of liquid carbon in the bulk carbon phase diagram, while conditions for the existence of liquid carbon can be achieved in the phase diagram for nanoscale carbon. Importantly, the Jouguet point of several powerful explosives is located in the region of liquid carbon in the nanocarbon phase diagrams, as confirmed by calculations of two different groups [8.20, 21, 60]. Pressures and temperatures at the Jouguet point (point A in Fig. 8.1) are not high enough to produce liquid bulk carbon, but they are high enough to produce liquid carbon at the nanoscale (Fig. 8.1). The region of liquid carbon is shifted to lower temperatures for nanocarbon, and the region of nanodiamond stability is slightly shifted to higher pressures (Fig. 8.1). Thus, it is suggested that nanodiamond is formed by homogeneous nucleation in the volume of supersaturated carbon vapor via condensation and crystallization of liquid carbon (Fig. 8.7). First, after decomposition of the explosive molecules (during ≈ 1 ns), primary carbon embryos (< 2 nm in size) are formed in the zone of chemical reaction (during ≈ 10 ns), followed by their coagulation into carbon droplets > 2 nm in size along the isentrope of expanding detonation products above 16.5 GPa (this stage lasts $\approx 10^2$ – 10^3 ns). Finally, nanodiamond particles are formed by crystallization of the liquid carbon droplets along the isentrope of expanding detonation products in the region 9–16.5 GPa (duration of this stage $> 10^3$ ns).

A mechanism for DND formation through crystallization of liquid carbon droplets formed from free carbon was also described in the work by *Viecelli and Ree* [8.60], who demonstrated that the Chapman–Jouguet states of all of the explosives fall in the liquid-phase region for carbon clusters with fewer than approximately 1000 atoms.

Further details on synthesis of DND can be found in books [8.49, 54, 59, 61] and reviews [8.7, 48, 62–64]. Recently, DND synthesis was revisited by several groups

with the purpose of addressing new demands on this material. Major focuses for novel approaches for DND synthesis are as follows:

1. Further reduction of the primary particle size
2. Control of the level of aggregation of DND at the synthesis stage
3. Increased sp^3 carbon content in detonation soot (in terms of reduction of noncarbon elements and sp^2 carbon on DND particle surfaces)
4. Doping of DND during synthesis, including control of the amount of substitutional nitrogen in the diamond core.

Reducing DND primary particle size down to the range of 1–3 nm may further increase their capability for penetrating cells and organelle membranes, including nuclear pores. ND particles with sizes ≈ 2 nm and smaller show quantum confinement effects [8.65]. Thus, synthesis of small particles would open perspectives for the development of diamond quantum dots. An increase of the ND specific surface area to a level comparable to that for carbon nanotubes would bring ND to the stage of perspective materials for hydrogen storage, catalyst support, fuel cells, and other applications.

In principle, the x-ray diffraction (XRD) data on the size distribution of primary DND particles within detonation soot, as reported in a limited number of publications [8.53, 66], include 2 nm peaks. It was reported by the *Dolmatov* group [8.66] that his novel method of using reducing agents (for example, urea, ammonia) in water cooling media allows preservation of the DND fraction with primary particle size less than 3 nm along with a typical fraction of 5 nm primary particles. In general, production of several classes of DND with average primary particle sizes from the 2 to 10 nm size range (for example, classes with 2–3, 4–5, and 10 nm average sizes) would be beneficial for various applications.

Also, a method reported in [8.66] using reducing agents provides the benefits of increased DND yield from soot (by 2–5 wt %) and overall yield of soot itself (by 100%) [8.66] as well as an increased carbon content (up to 96 mass %) within the DND particle composition, where the total content of C, H, N, and O corresponds to 100 mass %. A possible mechanism of action of the reducing agents in the cooling media is suggested to be as follows [8.66]: In the presence of reducing agents, the oxidants (the detonation products CO_2 , H_2O , O_2 , NO_2 , N_2O_3) interact primarily with the reducing agents, instead of oxidizing the carbon and particularly DND. This increases the yield of detonation soot and DND and quantitatively changes their

elemental composition, including carbon. Besides, the presence of readily oxidizable reducing agents among the detonation products helps to reduce graphitization of **DND**. Besides, the smallest amount of incombustible impurities (0.1–0.3 wt %) was found in **DND** synthesized in the presence of urotropine. This is due to the fact that urotropine is a strong complexing agent and captures impurities (metals Fe, Ni, Cr, Cu, Ti, etc.) to form soluble complexes which are easy to remove by subsequent chemical purification, i.e., treatment with nitric acid.

Another question is related to the possibility of optimizing the detonation process to produce mostly isolated primary particles and only small-size aggregates in the detonation soot. This would significantly reduce the cost of the final **DND** product. In fact, it has been recognized that dry **DND** synthesis results in smaller primary **DND** particle sizes and smaller average aggregate sizes as compared with wet synthesis. Another factor that influences the aggregation of **DND** during synthesis is the mass of the charge and the ratio between the masses of the charge and wet cooling media used [8.59].

Tailoring of **DND** electronic and optical properties for specific applications can be done at the stage of synthesis by development of different combinations of explosive materials with possible solid dopants, as well as using nontraditional cooling media (both gaseous and liquid) with possible additives to alter the **DND** composition (both bulk defects/doping content and surface groups). The possibility to control the N content by proper choice of the precursor material is discussed in the next section.

Structure of Different Types of Dynamically Synthesized Nanodiamonds

Recently, *Shenderova et al.* [8.67] carried out a thorough comparative analysis of the structure and composition of **ND** made by dynamic synthesis using the three major methods described above. Polycrystalline diamond from Microdiamant (produced by shock wave conversion of graphite) and from Real-Dzerzinsk (obtained from a graphite/RDX mixture), as well as detonation **ND** synthesized from different explosives were studied. Aggregates with sizes below 100 nm were chosen for the investigation. The phase composition and size distribution of the nanodiamond crystallites in the **ND** powders were analyzed by x-ray diffraction (**XRD**) and small-angle x-ray scattering (**SAXS**). For all samples, the diamond phase in the **XRD** patterns dominated. However, the presence of various amounts of graphitic

carbon was also observed (peak at $\approx 26.9^\circ$), being most pronounced in **ND** from Microdiamant. The diamond 111 diffraction peak was nonsymmetric due to overlap of the diamond 111 and graphite 101 peaks. The dimensions of the diamond crystallites were estimated from the Debye–Scherrer formula and were approximately 13.6 nm for the 111 reflection and 9.6 nm for the 110 peak for **ND** produced from graphite/RDX, 8 nm for **ND** obtained from graphite, and 4 nm for **DND** produced from explosives. A very rough estimation of the possible lonsdaleite grain size in Microdiamant's **ND** gives ≈ 2.4 nm.

For all samples the crystal size of the dominant fraction determined by **SAXS** was larger than the size determined from the broadening of the Bragg peaks. This difference originates in the different principles used for size determination in the two techniques. The width of the Bragg peaks in a **XRD** pattern reflects the size of so-called *coherently scattering domains*, which is usually smaller than (rarely equal to) the entire particle size. **SAXS** is based on the electron density contrast between the scatterer and the surrounding medium, thus providing information about the overall size of a nanodiamond particle. The discrepancy in the crystal size determined by the two techniques reflects the fact that diamond particles consist of several crystallites within a single grain.

The **SAXS** data for the **ND** from graphite sample showed a bimodal size distribution of the particles with peaks (diameters) at ≈ 6 nm (possibly graphite or lonsdaleite) and at ≈ 23 nm. The size distribution for the **ND** from graphite/RDX mixture possessed a relatively broad size distribution centered at ≈ 34 nm. Finally, the size distribution of the nanodiamonds produced from explosives (**TNT/RDX** and **TNT/HNS**) was typical for detonation nanodiamonds: the main peak showed diameters around 6 nm and a broad tail stretching out to larger sizes.

Figure 8.8 shows high-resolution **TEM** (**HRTEM**) images of the different **ND** samples. **ND** produced from graphite contained only abundant large, rounded or elongated diamond particles without a clear morphology (Fig. 8.8a). These structures often consist of agglomerates of smaller particles and show the presence of large amounts of defects in the diamond lattice. These particles can also be found in **ND** produced from a graphite/RDX mixture, but in combination with rounded or well-faceted polyhedral and truncated octahedral particles with low-index facets (Fig. 8.8b,c). The smaller **DND** particles below 6 nm in diameter show mainly (111) and (100) facets typical for small

Fig. 8.8a–d HRTEM images of ND synthesized by shock compression of graphite (a) and by detonation of graphite/RDX mixture (b–d) (after [8.67])

DND particles (Fig. 8.9a); larger particles also show higher-index facets (Fig. 8.9b). These particles show the presence of coherent $\Sigma = 3$ (111) twinning, common for detonation ND. Large, multiply twinned particles with diameters up to 100 nm can be found occasionally in DND samples (Fig. 8.9c).

Raman spectra of the samples were acquired in the range of $1200\text{--}1700\text{ cm}^{-1}$ (Fig. 8.10). Typically the first-order Raman spectrum of highly purified DND

consists of two peaks. The first one is located in the vicinity of 1332.5 cm^{-1} and corresponds to the vibrational mode of a diamond lattice from the center of its Brillouin zone. The origin of the second one observed at 1630 cm^{-1} is still a subject of debate. When an abundance of sp^2 -bonded carbon clusters is present in the ND, another two peaks characteristic for sp^2 carbon appear between 1350 and 1380 cm^{-1} (the D-band) and $1580\text{--}1610\text{ cm}^{-1}$ (the G-band). The G-band and D-band, obscuring the diamond peak in the ND produced from graphite, indicate a high content of sp^2 -bonded carbon in this sample. Large primary particles of the ND produced from graphite/RDX are not influenced by the phonon confinement effect, and the diamond line position is actually not shifted from the 1332.5 cm^{-1} position characteristic for the bulk material. All samples of detonation-type synthesis demonstrate a shift in the diamond Raman line down to 1328.5 cm^{-1} , which is explained by the phonon confinement effect observed for small nanocrystals [8.68].

Besides the morphological characteristics, of particular interest is the investigation of the effect of the type of synthesis on N content, N location in the ND core, and its ability to form optically active centers through the creation of complexes with vacancies. A scheme of the carbon-containing precursors for the three major methods of dynamic synthesis of nanodiamonds and factors influencing the nitrogen content in the produced nanodiamond material is presented in Fig. 8.11. In ND synthesis using explosives, N is an integral part of the high-energy explosive compounds. It can also be present as an impurity or an intentional dopant in graphite (or other carbon-containing materials) in the methods of dynamic synthesis involving bulk carbon precursors for ND production. The nitrogen content in

Fig. 8.9a–c HRTEM images of ND synthesized by detonation of TNT/RDX explosives. (a) The main fraction of DND particles has particle size close to 6 nm. Twinning is frequently observed in these small particles, with all visible twinning occurring along a (111) twin plane (examples of twin planes are indicated by white arrows in (a) and (b)). (b) Larger, multiple-twinned ND particle. An incoherent region is indicated by black arrows. (c) A rarely observed 100 nm octahedral particle. The inset electron diffraction ring pattern is typical for all DND samples and clearly evidences the cubic diamond crystal structure of all of the nanoparticles (after (a)[8.41], (b,c) [8.42])

the ND samples measured using combustion analysis indicated that the N concentration in the ND produced from a mixture of TNT/RDX explosives was higher than 2–2.5 wt %, that made from TNT/HNS was lower than 1%, and in ND made from graphite and graphite/RDX mixture it was lower than 0.5%. Thus, variations in the type of explosives can provide variation in the N content in the final ND product. It is possible that the N–N units of RDX (Fig. 8.11) contribute to enhanced N aggregation in the ND core, if they are not completely destroyed during detonation and are incorporated into the ND core as neighboring nitrogen atoms. Substituting RDX with HNS significantly reduces the N content. These issues require further study. Thus, variations in the type of explosives can be used together with the addition of other carbon precursor materials (for example, combination of graphite and HNS) to achieve the desired N content.

8.2.2 Survey of Laboratory-Scale Methods of Nanodiamond Synthesis

There are numerous reports on experimental observations of nanosized diamond, summarized in [8.48, 49]. In this section we provide a brief overview of nanodiamond particles synthesized on laboratory scale.

Milling of HPHT Microdiamond

The shape of diamond nanoparticles obtained by ball-milling of micrometer-sized HPHT or natural diamond particles typically have sharp edges and on HRTEM

Fig. 8.10 Raman spectra of dynamically synthesized ND samples (courtesy of I. Vlasov, General Institute of Physics, Moscow)

look like shattered glass particles [8.12]. Remarkably, ND particles with rounded shapes and particle sizes below 10 nm were recently obtained by a group of researchers starting with HPHT diamond [8.12]. The reported method is an important breakthrough in the production of single-digit ND containing NV centers, as it was demonstrated by the authors through processing of type Ib diamond. The initial raw material was a highly crystalline synthetic micrometer diamond powder (from Element Six) containing 80–100 mesh (150–190 μm) blocky, very uniformly shaped cubocta-

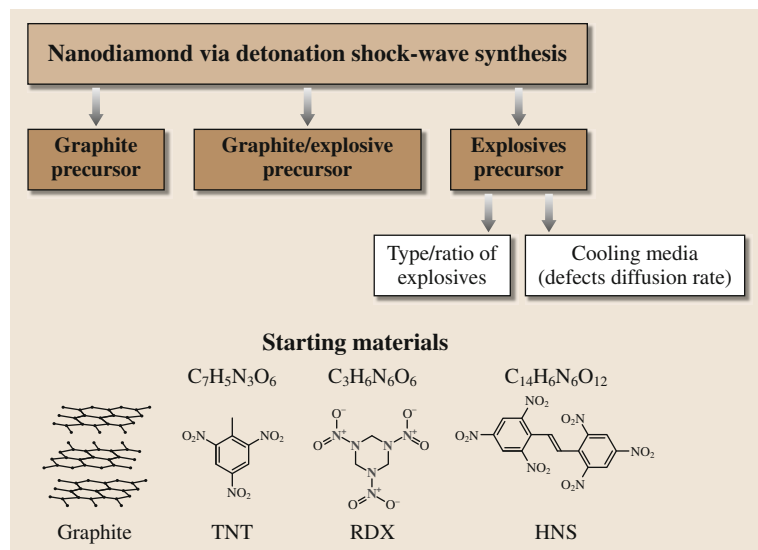

Fig. 8.11 A scheme of the carbon-containing precursors for the three major methods of dynamic synthesis of nanodiamonds and factors influencing the nitrogen content in the produced nanodiamond material

hedral diamond crystals. The first step included nitrogen jet milling micronization resulting in a powder with 97% of particles having sizes below 2 μm . Then an aliquot was ball-milled under argon using a planetary ball mill (Vario-Planetary Mill, Pulverisette 4; Fritsch, Germany), with 10 mm balls made of WC-Co cemented carbide for 24 h of effective grinding time. Nanodiamonds appeared as deformed polygons with quasispherical shape and an aspect ratio in the range 1.13–1.75. The overall yield of this method is about 15 wt % of the microdiamond mass converted into sub-10 nm diamond nanoparticles. The authors attribute the success of the production of the quasispherical particles to the complex loading regimes of the Vario planetary mill as compared with regular planetary mills.

HPHT Synthesis

While a particular class of nanodiamonds is obtained as a commercial byproduct of HPHT synthesis, there are laboratory studies of HPHT conversion of exotic carbon forms to nanodiamond. The HPHT process requires approximately 6 GPa pressure and 1500 °C to convert graphite powder into diamond in the presence of a catalyst. The use of exotic precursor materials such as fullerenes [8.69] as well as carbon nanotubes [8.70] allows much lower temperatures and externally applied pressures as compared with the use of graphite in order to synthesize diamond; for example, the transformation of buckyballs to diamond at high static pressure can be done at room temperature and does not require a catalyst at all [8.69]. Another group of authors reported the conversion of fullerenes to diamond under moderate conditions of 5.0–5.5 GPa and 1400 °C [8.71]. Carbon nanotubes have been converted to diamond at 4.5 GPa and 1300 °C using NiMnCo catalyst [8.70]. Based on HRTEM observations, the authors suggest that under HPHT conditions the tubular structures collapse and broken graphitic shells curl up and close into spheroidal networks to eliminate the dangling bonds at the edges.

Multi-walled carbon nanotubes were heated by a laser in a diamond anvil cell to above 17 GPa and 2500 K [8.72]. The recovered product consisted of nanosized octahedral crystals (diamond) of less than 50 nm. The tubular structure completely changed to granular, and the grain sizes corresponded to the diameter of the nanotubes. The grain size of the diamond suggests that the transformation took place by direct conversion of nanotubes, which might provide a means to control diamond size by choice of the multi-walled nanotube (MWNT) size.

An interesting implementation of HPHT treatment was reported by Soltamova et al. Sintering experiments were carried out on detonation ND with average particle size of 4.5 nm at temperatures of 1500–1700 °C and pressure of 6–7 GPa. According to the results of x-ray diffraction, the average size of the primary particles became 8.5 nm after sintering. When the sintering temperature is above 800 °C, vacancies start to diffuse. The presence of a significant amount of nitrogen-vacancy (NV) centers was detected in 10 μm aggregates using pulsed EPR [8.73]. The formation of NV centers can be possibly attributed to the combination of 1) elimination of surface paramagnetic centers and 2) vacancy diffusion from the high temperature of the process.

Nanodiamond Particles Synthesis Based on the CVD Technique

Frenklach and coworkers [8.74] studied the nucleation and growth of nanodiamond powder directly from the vapor phase in a substrate-free low-pressure microwave-plasma chemical vapor deposition (CVD) reactor. The particles were collected downstream of the reaction zone on a filter within the tubular flow reactor and were subjected to a wet oxidation to remove nondiamond carbon. The homogeneous diamond nucleation took place when dichloromethane- and trichloroethylene-oxygen mixtures were used as source material. The particles formed had crystalline shapes with average particle size around 50 nm. A mixture of diamond polytypes were observed in the powder.

Frenklach et al. [8.17] also studied the effects of heteroatom addition on the nucleation of solid carbon in a low-pressure plasma reactor. Addition of diborane (B_2H_6) resulted in substantial production of diamond particles, 5–450 nm in diameter, under the same conditions that show no diamond formation without the presence of diborane. The observed yield of the oxidation-resistant powder produced in boron-containing mixtures reached 1.3 mg/h. It was found that nanodiamonds in the CVD residue have an abundance of linear twins and star-twin microstructures consistent with radial (isotropic) gas-phase growth conditions. Studies of diamond nucleation directly from an activated gas phase have important implications in revealing mechanisms of interstellar dust formation.

Another example of homogeneous diamond nucleation in the gas phase is laser-induced decomposition of C_2H_4 at low pressures and temperatures that results in diamond powder formation with grain diameters of 6 nm–18 μm . According to the authors, the high-purity

homogeneously nucleated diamond nanoparticles had spherical and faceted morphology [8.75].

Ting et al. [8.76] developed a synthesis method for nanodiamond particles with 25–50 nm diameters using a microwave plasma torch system operating at near-atmospheric pressure. Gas mixtures of CH₄ with Ar or N₂ were used for ND particle synthesis, with Ar or N₂ serving as catalysts. Higher flow rate of Ar and N₂ or greater pressure in the reaction chamber produced larger nanoparticles.

The CVD technique was recently used for production of electrically conductive nanodiamond in particulate form by CVD growth of boron-doped nanodiamond films around a dielectric core of diamond nanoparticles [8.77]. Production of electroconductive boron-doped nanodiamond particles can be very beneficial and can find broad applications in high-surface-area carbon electrode materials for electroanalysis, electrochemical double-layer capacitors, storage materials for batteries, as a possible electrocatalyst support material for fuel cells, stationary support for liquid chromatography, and other applications [8.77].

Methods Using Radiation and High-Energetic Particles

Another group of methods for nanodiamond formation include direct transformation of carbon solids to nanodiamond. Recent experiments have shown that heavy-ion or electron irradiation induces nucleation of diamond crystallites inside concentric nested carbon fullerenes [8.15, 78]. High-energy electron irradiation (1.2 MeV, $> 10^{24}$ e/cm²; ≈ 100 dpa) was successfully used to convert the cores of concentric-shell graphitic onions into nanometer-size diamonds at irradiation temperatures above 900 K [8.15]. These experiments were performed in situ in an electron microscope, which allowed continuous observation of the formation process. A strong compression in the interior of the onion was inferred from the observed reduction in spacing between adjacent concentric shells during irradiation. Ion-beam irradiation of carbon solids also resulted in formation of nanodiamond [8.78]. Irradiation with Ne⁺ (3 MeV, 4×10^{19} cm⁻²; ≈ 600 dpa) at temperatures between 700 and 1100 °C converted graphitic carbon soot into nanometer-size diamonds [8.78]. Again, the diamonds were found to nucleate in the cores of graphitic onions that developed under irradiation. The increased diamond yield as compared with e-beam irradiation is explained by the higher displacement cross-section, the higher energy transfer, and the higher total beam current on the specimen. Other carbon materials can also

be transformed to nanodiamond by using a MeV electron or ion beams. ND nucleation occurs inside graphite under ion irradiation at ambient temperature when implanted with Kr⁺ ions (350 MeV, 6×10^{12} cm⁻²) [8.14]. The residue of the ion-irradiated graphite was found to contain nanodiamonds with average diameter of 7.5 nm. Another example of nanodiamond formation includes irradiation of highly oriented pyrolytic graphite surfaces using a highly charged ion (HCI) [8.79].

Laser-Assisted Synthesis of Nanodiamond Particles

Generation of nanoparticles by laser ablation in liquids is a relatively new approach that has been actively explored during the last decade [8.80]. It has a number of important advantages over conventional multistep chemical synthesis methods that introduce contamination from the intermediate reactants and/or produce agglomerated structures with degraded functionality. The direct laser ablation eliminates the need for chemical precursors and enables generation of *clean* nanoparticles. Due to the highly nonequilibrium nature of the laser ablation process, the structure and composition of nanoparticles produced by laser ablation can be very far from the equilibrium ones, opening an exciting range of opportunities for generation of novel nanostructures with unique properties.

Nanocrystalline diamond has also been produced by pulsed laser ablation using a graphite target along with water or acetone as the liquid medium [8.80]. The authors suggested that OH groups formed from the oxygen-containing liquids etched nanodiamond carbon species from the surface, thereby allowing diamond to form preferentially. Diamond nanocrystals have been produced by pulsed laser ablation of graphite at room temperature and pressure in two liquids (water and cyclohexane) by Pearce et al. [8.81]. The nanodiamond formation was attributed to the extreme temperature/pressure conditions created by collapse of bubbles. The sequence of processes in laser ablation of liquids is likely to include explosive decomposition of the overheated surface region of the absorbing target, ejection of clusters and vapor into the surrounding liquid, mixing of the ejected ablation plume with the liquid and bringing the liquid to boiling or supercritical states, and growth and solidification of the nanoparticles under conditions of fast quenching. The final size, structure, and composition of the produced nanoparticles are defined by the heat and mass transfer occurring under highly nonequilibrium, quickly evolving conditions that are poorly understood at this time. Nanodiamond par-

ticles have been also synthesized from fine particles of carbon black exposed to intense laser irradiation [8.82]. Similarly, the transformation from carbon nanotubes to carbon onions and then to nanodiamond as a result of laser irradiation has been reported [8.83].

Diamond Synthesis Using Ultrasound Cavitation

The temperatures and pressures required for synthesis of diamond material can be achieved by different means, including ultrasound cavitation as a result of the rapid collapse of cavitation bubbles generated in a suitable liquid medium [8.84]. Depending upon the cavitation conditions, the pressure and temperature inside the cavity at the moment of collapse may reach extremely high instantaneous values: $\approx 10^5$ – 10^6 bar and 1000 K, respectively [8.85]. Two research groups reported the formation of nanostructured [8.86] and monocrystalline [8.87] micrometer-sized diamond particles. Cavitation destruction of benzene resulted in production of particles consisting of aggregates of nanocrystallites of 10–30 nm in size [8.86]. Micrometer-sized diamond crystals (5–10 μm) were produced by the cavitation synthesis method from a suspension of powdered graphite (100–200 μm) in organic liquid [8.87]. The major factor influencing the diamond yield in the cavitation process was the composition of the cavitation medium. The diamond yield was about 10% of the ini-

tial graphite weight. As cavitation fluids, a series of aromatic C–H–O oligomers with low saturated vapor pressure and high boiling temperatures were used.

Carbide-Derived Diamond

Selective etching of carbides is an attractive technique for the synthesis of various carbon structures including nanocrystalline diamond [8.13, 45, 88]. Carbon produced by extraction of metals from carbides is called carbide-derived carbon [8.88]. As summarized in [8.88], leaching in supercritical water, high-temperature treatment in halogens, vacuum decomposition, and other methods can be used to remove metals from carbides to produce carbon coatings or bulk and powdered carbon. In principle, chlorination of carbides for the production of carbon-based materials and, particularly, nanoporous carbon is a relatively mature technology that has been commercialized. However, the synthesis of nanocrystalline diamond by this technique [8.13] is a recent achievement. Particularly, during extraction of silicon from silicon carbide or metal carbide using chlorine-containing gases at ambient pressure and temperatures not exceeding 1000 °C [8.45], nanocrystalline diamond with average crystallite size of 5 nm was formed. Nanocrystalline diamond is usually surrounded by amorphous carbon.

8.3 Detonation Nanodiamond Processing and Modification

The three major steps in the conversion of carbon-containing explosives to DND products include synthesis, postsynthesis processing, and modification, which are discussed in detail in the following sections. Postsynthesis processing includes purification of detonation soot from metallic impurities and nondiamond carbon and is typically performed in conjunction with detonation soot synthesis by the same vendor. The result of the processing is DND of a certain purity (presently at a level of incombustible impurity content 0.5–5 wt % depending on the vendor) that is available on a large scale (thousands of kilograms). DND treatments, tentatively called modification, can include additional deep purification, surface functionalization toward specific applications, and deagglomeration or size fractionation. In the last 3–4 years, the development of approaches for DND modifications has been the major focus of research activity. Although initially DND modifications were performed on a small scale, currently these steps

are being implemented on a large scale at DND production centers [8.89]. Of primary importance is the method of disintegration of nanodiamond aggregates by stirred-media milling with micrometer-sized ceramic beads as suggested by Osawa and coworkers [8.90], resulting in diamond slurries containing primary 4–5 nm DND particles. This single-digit DND immediately attracted the attention of a relatively large number of researchers working in the area of nanoscale materials, as demonstrated by recent publications [8.91].

8.3.1 Postsynthesis Processing

The development of DND products of ultrahigh purity remains an important goal for many applications. In addition to the diamond phase, the detonation soot contains both graphite-like structures (25–55 wt %) and incombustible impurities (metals and their oxides – 1–8 wt %) [8.92]. The metal impurities orig-

inate from the detonator and from the walls of the detonation chamber. After typical purification steps, powders of DND can be considered a composite consisting of different forms of carbon (≈ 80 – 89%), nitrogen (≈ 2 – 3%), hydrogen (≈ 0.5 – 1.5%), oxygen (up to $\approx 10\%$), and an incombustible residue (≈ 0.5 – 8%) [8.62]. The carbon phase consists of a mixture of diamond (90 – 99%) and nondiamond carbon (1 – 10%).

Both nondiamond carbon and metallic, incombustible impurities can be located externally or internally relative to the tight DND aggregates. In order to remove the internal metal impurities and internal nondiamond carbon, tight DND agglomerates should be disintegrated. Currently, detonation soot can be industrially purified to a level of remaining incombustible impurities of about 0.5 – 0.6 wt %. In general, methods of DND purification as well as DND purity vary from vendor to vendor [8.62]. Classical purification methods, based upon the use of liquid oxidizers for the removal of metallic impurities, include sulfuric acid, a mixture of sulfuric and nitric acids, hydrochloric acid, potassium dichromate in sulfuric acid, as well as other schemes. A brief review on the numerous methods of detonation soot purification developed in the former USSR is provided in [8.93]. For the oxidation of sp^2 carbons, the purification schemes include KOH/ KNO_3 , Na_2O_2 , CrO_3/H_2SO_4 , HNO_3/H_2O_2 under pressure, mixtures of concentrated sulfuric and perchloric acids, and other approaches [8.62]. To remove noncarbon impurities, the chemically purified product is subjected, in some cases, to an additional purification process using ion-exchange and membrane technologies. Currently, the majority of DND vendors use strong liquid oxidizers at elevated temperatures and pressures. However, liquid-phase purification is both hazardous and costly, contributing up to 40% of the product cost. Alternatively, DND can be very effectively purified from nondiamond carbon in a more environmentally friendly manner by a gas-phase treatment using ozone at elevated temperatures [8.94] to eliminate the need for use of corrosive liquid oxidizers. Ozone is generated using corona discharge at the input of the reactor and is destroyed at the output of the gas flow. Ozone oxidation is more efficient for sp^2 carbon oxidation than oxygen. Such ozone-modified nanodiamonds (NDO) were found to have a number of distinctive characteristics. The size of polydispersed NDO in water suspensions is about 160 – 180 nm, as measured by dynamic light scattering technique. This number is the smallest average size reported for commercially available polydispersed unfractionated DND.

In addition, the content of the primary, polyhedrally shaped, faceted particles with size of 3 – 5 nm in the polydispersed NDO is substantially higher than that of acid-purified DNDs. The NDO hydrosols were found to possess a very low pH (1.6 – 2 for 10% hydrosol) and low negative zeta potential (-50 mV for polydispersed sample and down to -100 mV for 20 – 30 nm fraction) and to feature a constant zeta potential (≈ -40 to -50 mV) over a wide pH range of 2 – 12 , apparently due to enrichment of the surface with oxygen-containing strong-acid groups. HRTEM imaging of NDO particles demonstrated low sp^2 content, and electron energy-loss spectroscopy (EELS) studies demonstrated lower content of sp^2 carbon in NDO as compared with ND purified using etching in hydrogen, as well as with other types of DND [8.95].

Several efforts have been made to purify DND by oxidation of detonation soot with air at elevated temperatures. The method allowed for a significant decrease in the nondiamond carbon content. Larionova et al. purified DND using soot treatment with air at 380 – 440°C for several hours [8.96]. Soot purification through a combination of liquid oxidizers and air treatment at temperatures up to 600°C was reported by Mitev et al. [8.97]. Osswald et al. [8.98] demonstrated that for soot the optimal temperature for the heat treatment in air within several hours is 400 – 430°C .

8.3.2 Nanodiamond Deagglomeration and Fractionation

DND obtained from commercial vendors often requires additional processing and modification, since the content of incombustible impurities and nondiamond carbon can be too high, with an average aggregate size that is too large and with surface chemistry that is not suitable for a specific application. Poor colloidal stability of commercially available DND powders after liquid dispersion is a common problem. Besides, there is no universal material called *detonation nanodiamond*, since materials properties are specific to the synthesis and postsynthesis purification methods adopted by the vendor. As a means to improve the quality of the DND product, methods of fractionation and deaggregation are discussed below.

While the primary DND particle size is 4 – 5 nm, the primary particles form tightly and loosely bound aggregates. Typical commercial polydispersed ND suspensions that are subjected to powerful ultrasound treatments routinely exhibit 200 – 400 nm average aggregate sizes, which are unbreakable by the ultrasonic

treatment. An approach to effectively separate the particles to achieve a narrow size distribution is centrifugal fractionation [8.89, 99, 100]. Importantly, DND suspensions must possess high colloidal stability for centrifugal fractionation. It is not possible to fractionate an unstable suspension.

DND fractionation has several attractive aspects. First, it is a contamination-free approach as compared, for example, with bead milling, which introduces impurities from the ceramic beads which require further purification [8.4]. It is also convenient to be able to fractionate DND into different, narrow size distributions for different niche applications; for example, only DND with aggregate sizes of more than 100 nm can form photonic structures that diffract light in the visible region [8.101]. Finally, after deep purification or treatment with ozone/air, the content of DND with small-sized aggregates can be significantly increased and the production of suspensions with small fractions of pure DND without added contaminants becomes economically feasible. In fact, suspensions of 5 wt % of 25 nm-size DND fraction in water have been produced using the fractionation method [8.89]. Importantly, it is possible to extract only primary DND particles by centrifugal fractionation, including ultracentrifugation [8.102].

Deagglomeration of nanodiamond aggregates into individual primary particles is an important goal for a variety of applications. Methods of mechanical deagglomeration of DND dispersion in suspensions by stirred-media milling [8.4] or bead-assisted sonic disintegration [8.103] were developed, and suspensions of individual 4–5 nm DND particles have been produced.

Undesirable side-effects from bead milling include contamination with the bead material and generation of graphitic layers on the particle surface [8.4]. Attempts to purify bead-milled DND with liquid oxidizers led to aggregation of the primary particles [8.4]. Fortunately, by optimizing the bead-milling process, it is possible to minimize the contamination by the bead-milling media to below 0.2%. Purification from the bead-milled material using NaOH solution in water was considered [8.104] as well as molten NaOH. In addition, amorphous carbon and metal contaminants confined within DND aggregates and released during bead milling also need to be removed from the resulting suspension of primary particles. Nevertheless, production in kilogram quantities of this so-called Nanoamando nanodiamond has been started. Nanoamando has become a very popular nanodiamond

material for biomedical research and has permitted successful development of applications.

A novel method of ND deaggregation by salt- or sugar-assisted dry milling was recently explored and yielded 5–20 nm ND particles with much fewer impurities than the bead-milling method [8.105].

Several other methods have been proposed for DND deagglomeration. Xu et al. developed a two-step deagglomeration procedure that included graphitization of byproducts of detonation in N₂ atmosphere at 1000 °C for 1 h followed by their oxidation with air at 450 °C for several hours [8.106]. The final powdered product contained at least 50% DND with particle size of less than 50 nm. Krueger reported using DND reduced in borane (accompanied by ultrasonic treatment), resulting in significantly smaller-sized aggregates [8.107]. Treatment of DND powder in an atmospheric pressure plasma also reduced the average DND aggregate size by ≈ 20% [8.108].

A concern that requires thorough study is the possible reagglomeration of single-digit DND or small-sized fractions subjected to further surface functionalization or drying for storage. Typically, during drying of ND from water and other solvents, ND aggregation is further increased due to capillary forces pulling together individual particles. Attractive van der Waals forces also play a major role in particle agglomeration. Agglomeration during drying makes ND functionalization more difficult, since it often requires dry starting ND material. Puzyr and Bondar has developed a modification based upon sonication-assisted treatment of ND in NaCl solution [8.109], which results in purification of the ND and possibly the incorporation of Na⁺ ions into the ND surface. The attractive feature of the NaCl treatment method of ND modification [8.109] is the possibility of drying NDs from a hydrosol to a powder form with subsequent resuspension without agglomeration. DND powder with average aggregate size ≈ 40 nm after dispersion in water was obtained through this method.

8.3.3 ND Surface Functionalization

Among the two main types of nanodiamonds, i. e., DND and HPHT ND, DND are unique in their diversity of surface chemical functional groups generated in the detonation process. DND particles consist of a surface containing a wide variety of chemical functional groups surrounding a diamond core. This chemical *soup* may include well-known groups such as carboxylic acids, esters, ethers, lactones, and amines. While the diversity

of these functional groups is large, the density of surface groups as a function of particle size is also large. The **DND** primary particle size is small ($\approx 4\text{--}5\text{ nm}$), and thus they have a large surface area-to-volume ratio. For **HPHT ND**, the nanoscale diamond powders are in the size range of $25\text{--}30\text{ nm}$. Therefore, the amount of functional chemical groups per unit mass of **DND** exceeds by several times the functionalization capacity of nanoscale diamond powders. **DNDs** may be thought of as solid-phase chemical libraries; they are solvent-accessible, highly dense, and chemically rich arrays positioned on a physically and chemically stable diamond platform. Conveniently, this chemical array can also be readily modified using standard wet chemical synthesis. Also, the hydrophilic nature of **DNDs** is important in applying these particles for applications in chemistry and biology. In fact, **DNDs** readily adsorb water from air, which requires the use of vacuum desorption Fourier-transform infrared (FTIR) spectroscopy to unmask chemical functional groups that are located at the same frequency as water groups [8.110]. Water and dimethylsulfoxide (**DMSO**) are excellent solvents

for **DNDs** and allow for stable, highly concentrated colloidal suspensions. It is well known that **DNDs** function as an adsorbent, collecting toxins (enterosorbents), proteins, peptides, polysaccharides, antibodies, nucleic acids, viruses, and bacteria.

There are several processing steps that may be taken in chemically modifying nanodiamonds. For nanodiamonds of detonation origin, soot is initially produced in the synthesis. To obtain **DNDs**, the soot is purified to remove metallic and nondiamond carbon contaminants. Purification procedures are optimized to produce nanoparticles that have a high density of charge, in order to form stable colloidal suspensions. To further improve the colloidal stability, enrichment of carboxylic acid groups on the nanodiamond surface can be achieved by oxidation with ozone or by thermal annealing in air at temperatures above 400°C [8.98]. This treatment yields solutions with a negative zeta potential. Conversely, **DND** surfaces may be reduced to enrich the surface with hydroxyl chemical groups using either borane or lithium aluminum hydride [8.110, 111], producing positive zeta potentials.

Eppendorf tubes after thorough rinsing of the **ND** pellet with water using aminated **ND** (**ND-NH₂**) and either **TAMRA** dye alone (top row) or reactive **TAMRA-NHS** (**NHS** – *N*-hydroxysuccinimidyl ester) (bottom row). Photographs of strongly photoluminescent dye on **ND** (right) and physisorbed dye (left) taken with a fluorescent microscope using illumination with green light

Covalent Bonding

In recent years, extensive chemical synthesis has been done on nanodiamonds [8.112]. As compared with **DNDs**, chemical modification of **HPHT NDs** is more difficult. Some reaction chemistries for **HPHT NDs** that have been used include radical chemistry conjugation using small molecules to conjugate aromatic-NO₂ surface groups [8.113, 114] and carboxylic acids [8.115]. Fluorine surfaces on nanodiamond films can be created by photolysis [8.116] or by cold plasma with fluorine gases [8.117]. Fluorinated **HPHT** nanodiamond particles may be converted to alkyl, amino, and amino acid derivatives [8.118].

For **DND**, standard wet chemical synthesis methods are available for grafting chemical groups onto its surface. One of the most useful nanodiamond conjugates is aminated **ND**. Several different pathways have been used to create aminated **DND**. In one method, silanization of **ND-OH** using aminopropyltrimethoxysilane (**APES**) produced aminated **ND** for attaching peptides [8.111], biotin [8.107], dyes [8.119], and protein-capturing aminophenylboronic acid [8.120]. A second method to produce aminated **DND** (Fig. 8.13), used standard wet chemical synthesis that required four reaction steps. This method produced aminated **ND** that was

colloidally stable in water and was used to bond biotin and **TAMRA** (tetramethylrhodamine) dye moieties with their succinimidyl ester conjugates, producing stable amide linkages [8.110]. The third method for amination requires only a two-step reaction from **ND-COOH**, whereby the COOH is converted to an acyl chloride and then reacted with octadecylamine. Surprisingly, this modified **DND** was fluorescent blue in hydrophobic solvents [8.121].

Loh et al. showed that the Suzuki coupling reaction can be used to prepare biaryl-functionalized **DNDs**. Initially, a bromophenyldiazonium salt is coupled onto the hydrogenated **DND** surface, producing a bromophenyl **DND** synthon. This synthon undergoes Suzuki coupling with an aryl boronic acid moiety, resulting in a biaryl-functionalized compound. The broad applicability of this reaction means that it is used to prepare drugs for pharmaceuticals and for attaching different aryl moieties, such as fluorescent dyes, onto a range of substrates. Here the coupling was used to graft a functionalized fluorescent dye using the reaction of a commercially available pyrene boronic acid derivative to a bromophenyl-functionalized **DND**. The Suzuki reaction can also improve the colloidal stability of **DNDs** in organic solvents, since they

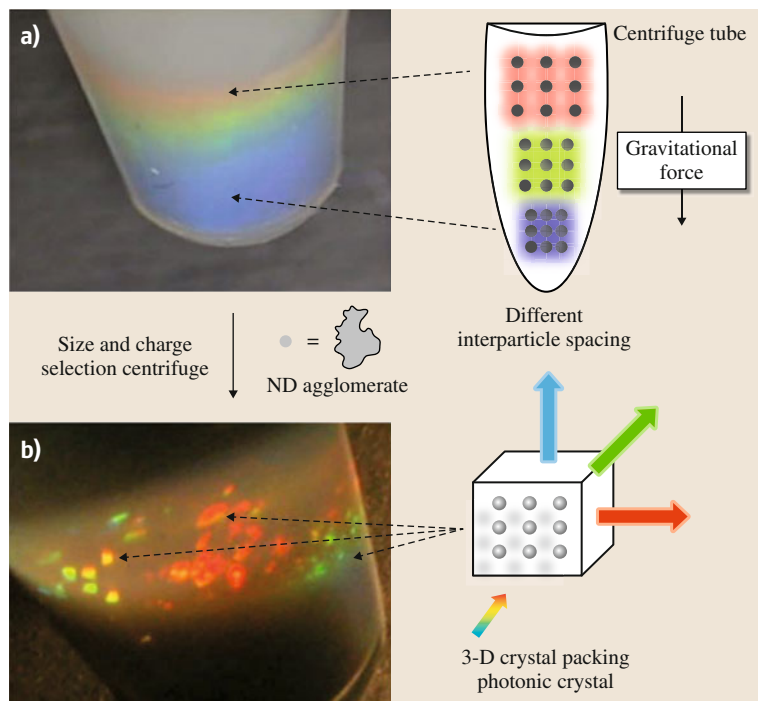

Fig. 8.13a,b Photographs showing that nanodiamonds form a rainbow pattern of colors that is dependent upon the interparticle spacing: wide spacing (*red band*) or close spacing (*blue band*) (**a**). Continued washing by centrifugation produces discrete, bright, millimeter-sized photonic crystals that are ordered in 3-D space (**b**)

readily form hydrophobic aryl compounds, such as trifluoromethylaryl-functionalized **DND** for colloidal stability in ethanol and hexane [8.122].

Recently, Krueger et al. have been successful in using several standard wet chemical synthetic methods applied to nanodiamonds after some surface conversion of sp^2 character [8.112]. These reactions are adopted from carbon nanotube and fullerene chemistry, based upon the reactivity of the C–H bond from sp^2 -functionalized carbon surfaces. Initially, nanodiamonds are produced by thermal annealing (**DND** and **HPHT**) or ball-milling (**DND**) nanodiamonds. These arylation reactions include (briefly):

1. C–C coupling reactions with aryl diazonium compounds [8.123]
2. 1,3-Dipolar cycloaddition using the Prato reaction [8.124]
3. Cycloaddition using the Diels–Alder reaction [8.125]
4. *Click* chemistry using the product from the diazotization of primary amines [8.126].

These reactions are described in more detail here. In the first reaction, Krueger et al. used the diamond C=C of sp^2 carbons of thermally annealed **DNDs** to prepare **DNDs** bearing either hydrophilic (COOH, SO₃H) or hydrophobic (NO₂, CH₂CH₂Br) groups by using suitably substituted anilines that were converted to their reactive diazo salt. These aryl-functionalized groups formed stable colloidal suspensions in water (COOH, SO₃H) and acetone (NO₂, CH₂CH₂Br). Importantly, the aryl-COOH-functionalized **DND** is stable in phosphate-buffered saline. This unique property of nanodiamond paves the way for realizing biomedical applications with **DND** [8.123].

In the second reaction, Krueger et al. demonstrated a general approach for **DND** surface grafting by using the Prato reaction in which a pyrrolidine ring as the linking moiety is formed in the presence of sp^2 carbons from the **DND** surface. This is a versatile reaction that allows grafting of both alkyl and aromatic side-chains that can be achieved under mild conditions. This reaction uses sarcosine (*N*-methylglycine) and a number of aldehydes to generate azomethine ylides in situ. The 1,3-cycloaddition reaction produced a variety of substituted pyrrolidine rings, including rings with oligo-ethyleneglycol chains, aromatic moieties, and reactive groups such as the cyano group [8.124].

In the third reaction, Krueger et al. used the classic Diels–Alder cycloaddition reaction using *o*-

quinodimethane, which acts as a diene, on the π C=C bond of sp^2 carbons of **DND**. This reaction is simple and allows for another method for conjugating **DND** surfaces with many different substitution patterns. In one example, a thiol-functionalized product was used to conjugate Oregon Green dye which carried a maleimide group by using the maleimide-thiol reaction onto the **DND** surface [8.125].

In the fourth reaction, Krueger et al. used the popular *click* chemistry carried out with the sp^2 surface of nanodiamonds, which allowed for both high product yield and reactivity under aqueous conditions. It was demonstrated that the addition of sp^2 surfaces on **HPHT ND** and **DND** (by either thermal annealing or mechanical milling) increases the surface coverage of reactive groups useful for *click* chemistry reactions. Similar to previous work, a diazotization reaction was used to bind the diamond surface, whereby the primary amine was *para*-substituted with either an azide or an alkyne [8.123]. Next, the *click* reaction proceeded using the coupling of the azide/alkyne. An orthogonally functionalized **DND**, modified with two different reactive groups (COOH and alkyne), was used to conjugate differently colored dyes. First, the COOH was used to produce an amide bond to bind Oregon Green, which was followed by a *click* reaction of the **ND**-alkyne to the azide of **TAMRA** [8.126].

Polymeric reactions on the **ND** surface have been achieved with a number of different methods. Using thermally annealed **HPHT NDs**, Chang et al. functionalized the sp^2 carbon layer with polymers using a radical initiator in under 10 min using ultrasonication and microwave heating. The oligomer side-chains on the **HPHT NDs** were either hydrophilic (amines, carboxylic acids) or hydrophobic (alkyls, phenyl) [8.127]. Copolymers of methyl methacrylate, styrene, and an acrylamide were grafted on **NDs** using ferrocene [8.128]. Hydrophobic and hydrophilic polymer brushes have been prepared by atom-transfer radical polymerization from the carboxylated **DND** and methacrylate esters [8.129]. These polymer brushes provide exceptional properties to **DNDs**, which have a low number of reactive sites for the high surface area.

Noncovalent Binding

DND surfaces have been modified by electrostatic binding. Due to the charged nature of **DNDs**, attachment by electrostatics alone can be achieved for small molecule dyes [8.108] and proteins such as insulin [8.130]. When condensation does not occur on its own, additives can be used to facilitate the binding; for example,

small molecules can be condensed onto DNDs with the addition of salts for the chemotherapeutic drugs doxorubicin [8.91, 131] and 10-hydroxycamptothecin [8.132]. This mechanism of binding allows for the release of the drugs under certain ionic conditions. In addition to using salts, charged polymers can be used. DNDs have been adsorbed with cationic polymers, such as poly-L-lysine, to negatively charged DND. The advantage of using poly-L-lysine is that it enriches the DND surface with a high density of amine groups, commonly used for biofunctionalization chemistries; for example,

succinimidyl ester conjugate dyes and proteins may be chemically linked to these amine groups on the DND surface [8.133, 134]. Heterofunctional linkers have also been used to bind the cytochrome c protein to poly-L-lysine-coated DND, providing up to two molecules of protein for a 5 nm particle [8.133]. In addition, polycationic polyethylenimine was used to condense silenced RNA (siRNA) onto DNDs [8.135], whereas cationic polylysine-coated [8.134] or a methacrylate cationic polybrush [8.136] was used to adsorb DNA plasmids.

8.4 Fluorescent Nanodiamonds

The presence of nitrogen-vacancy (NV) centers – a nitrogen atom next to a vacancy – in nanodiamond leads to useful fluorescence properties. A central focus of many research groups remains the controlled production of nitrogen-vacancy centers in nanoscale diamond. Due to the strong optical transition, single defects can be detected using a fluorescence microscope. The spin state of the negatively charged NV centers permits the implementation of efficient single-photon emitters for quantum information processing [8.5] or magnetic sensors with nanoscale resolution [8.6]. Single color centers show outstandingly high photostability, even at room temperature [8.11]. Thus, on-demand production of NV centers in nanodiamond is important for several emerging applications such as quantum information, nanoscale sensing, and photoluminescent markers for microscopy.

NV centers can be created by irradiating nanodiamond with high-energy particles (electrons, protons, helium ions), followed by vacuum annealing at 600–800 °C [8.11]. Irradiation forms vacancies in the diamond structure, and during annealing these vacancies migrate and get trapped by the nitrogen atoms that are always present in diamond. Two types of NV centers are formed – neutral (NV⁰) and negatively charged (NV[−]) – and these have different emission spectra. The NV[−] center is of particular interest because it has a $S = 1$ spin ground state that can be spin-polarized by optical pumping and manipulated using electron paramagnetic resonance (EPR). Moreover, it has a long spin coherence time [8.5]. Fluorescent NV centers in isotopically clean diamond are of particular interest for quantum computing [8.137], while NV centers in nanodiamond are also being investigated for applications in high-resolution magnetic sensing [8.6, 138, 139],

fluorescence resonance energy transfer [8.140], and biomedical imaging [8.11].

The development of bright photoluminescent nanodiamonds has been mostly done on materials produced by high-pressure high-temperature synthesis [8.11, 12] containing up to hundreds of parts per million of native substitutional nitrogen, which are then crushed down to nanosized particles, including single-digit nanodiamonds [8.12]. While the concentration of the fluorescent NV defects produced by electron irradiation does not depend on the size of the nanocrystals [8.141], the fraction of NV[−] defects produced by the same technique decreases with the size of the nanodiamond [8.142], presumably due to electron traps located at the surface.

While 7 nm HPHT ND particles have been obtained on laboratory scale [8.12], 20 nm particles are the only commercially available fraction of HPHT ND (for example, from Van Mopes, Co.). Cost is also an important factor in nanodiamond particle applications. Cost of HPHT ND ground to nanometer sizes is an order of magnitude higher than that of deagglomerated detonation nanodiamond.

Up to now, nanodiamond synthesized from explosives was not amongst the preferred candidates for imaging applications based on NV centers. Recently, intermittent luminescence originating from NV centers was observed in individual pristine 5 nm detonation nanodiamonds (DND) produced from TNT/hexogen precursor [8.139]. Stable luminescence has also recently been detected from NV centers trapped in larger (> 20 nm) nanodiamonds produced from TNT/hexogen [8.42] and graphite/hexogen [8.67] precursors. These results suggest that various factors (such as the amount of nitrogen in the precursors and the cooling

conditions) have a role in the nitrogen incorporation into the nanodiamond core and in possible in situ formation of NV centers. Size-related proximity of surface defects and the presence of numerous internal defects might contribute to the low fluorescence intensity of nanodiamond produced from explosives. This is supported by the demonstration of a very high content (up to 1%) of NV defects in detonation nanodiamond after sintering at $T = 800^\circ\text{C}$ and $P = 6\text{ GPa}$ [8.143], enlarging nanodiamond sizes.

Fluorescent particles can also be produced by linking [8.110] or adsorbing [8.133] various fluorophores onto nanodiamond. Fluorophore-conjugated nanodia-

mond can travel through cellular compartments of varying pH without degradation of the surface-conjugated fluorophore or alteration of cell viability over extended periods of time [8.144]. Bright-blue fluorescent nanodiamond was recently produced via covalent linking of octadecylamine to carboxylic groups on the nanodiamond surface [8.121].

Fluorescent nanodiamonds combine the advantages of semiconductor quantum dots (small size, high photostability, bright multicolor fluorescence) with biocompatibility, nontoxicity, and rich surface chemistry, which means that they have the potential to revolutionize in vivo imaging applications [8.11, 145, 146].

8.5 Applications of Nanodiamond Particles

The market for nanodiamond particles has been expanding rapidly worldwide following the release of previously tightly held information by the former USSR related to detonation nanodiamonds. Consumption of DND is still largely centered around many of the core applications identified in the former USSR: additives to galvanic coatings, polishing and lubricant additives [8.48, 62]. Marketing has made industries around the world aware of the applications where DND provides benefit through enhancement of material properties in a wide range of applications. Below we survey selected applications which benefit from the property of nanodiamond as a superhard additive as well as its biocompatibility, nontoxicity, and rich surface chemistry. This survey is far from being comprehensive and is intended to provide a flavor of this rapidly growing field.

8.5.1 Nanodiamond in Polishing Applications

Polycrystalline diamond particles produced by shock conversion of graphite or detonation of a graphite/RDX mixture have been steadily consumed for several decades as micrometer-sized particles for lapping and polishing. In this capacity micrometer-sized diamond is indispensable despite its high cost (more than US\$6/g), providing a high removal rate during polishing of hard carbide and nitrate substrates for microelectronic devices. For the fine finish polishing, requiring abrasives of sub-100 nm size, much less expensive colloidal silica is widely used. It was recently reported, however, that a combination of colloidal sil-

ica and nanosized diamond particles can provide the most beneficial effect through an increase in polishing rates, leading to a reduction in production time and surface finish better than 4 \AA (Nanodiamond Product, Ltd., Ireland [8.147]). Since the amount of nanodiamond added is low ($\approx 10\%$), the cost of the synergistic composition is increased insignificantly; For example, An et al. [8.147] investigated the effect of addition of nanosized diamond slurry (grain size 25 nm) into conventional KOH-based colloidal silica slurry for chemical-mechanical planarization (CMP) of SiC materials. Addition of the nanodiamond slurry resulted in surface roughness of $R_a \approx 2.2\text{ \AA}$ (after 1 h of polishing) as compared with 5.9 \AA when colloidal silica alone was used. Moreover, addition of a strong oxidizer NaOCl into the ND-silica composition resulted in a material removal rate (MRR) of 0.3 mg/h (versus 0.06 mg/h in the slurry without NaOCl) and $R_a \approx 1.08\text{ \AA}$. The improvement in the R_a and MRR after addition of ND particles can be explained as follows. Colloidal silica acts as a wet-chemical surface oxidizer that generates a SiO_2 layer on the SiC surface and etches the surface to reveal the damaged layer from mechanical polishing. The nanodiamond particles remove (abrade) the silica layer, increasing the MRR, and polish the damaged layer revealed by KOH-based colloidal silica slurry, decreasing R_a . Addition of NaOCl further enhances the chemical reaction on the SiC surface with KOH-based colloidal silica, producing a much thicker SiO_2 layer which can be efficiently removed by ND particles. Nanodiamond Products, Ltd. report that nanodiamond additive to colloidal silica enhances production of electronic substrate materials such as sapphire, silicon carbide (4H/6H

polytypes), silicon nitride, and gallium nitride, lithium niobate, gallium arsenide, calcium fluoride windows, fiber-optical bundle ends for greater data transmission, liquid-crystal displays (LCD), and light-emitting diode (LED)/organic LED (OLED) displays. The addition of a nanodiamond slurry to existing colloidal solutions is also used for metallographic polishing.

8.5.2 ND Applications in Composites

A broad area of application of nanodiamonds utilizing their high chemical inertness and superhardness is incorporation of DND into different matrixes and production of composites. Numerous applications of DND-based nanocomposites are under development, including wear-resistant additives to metal coatings; antifriction additives to lubricants and oils; polymer nanocomposites and coatings with enhanced strength, impact resistance, and scratch resistance; and nanocomposites with improved thermal stability and thermal conductivity. An example of nontraditional applications includes demonstration that nanodiamond particles in a polydimethylsiloxane matrix attain very pronounced photoluminescent when irradiated with a flux of MeV protons [8.148]. This suggests application of the ND-polymer coatings as fluorescence-induced indicators of acquired proton dose, for example, by spacecraft that is exposed to irradiation of protons. Other examples include fabrication of novel composites of carbon nanotubes incorporated into a nanodiamond matrix [8.149, 150], photonic structures made of DND [8.151], and DND-based ultraviolet (UV)-protection coatings and sunscreens [8.152]. Also, DNDs serve as a source material for production of onion-like carbon (OLC) by high-temperature annealing of DND in an inert atmosphere. Recently it was demonstrated that OLCs are strong absorbers of electromagnetic (EM) radiation from the gigahertz, to terahertz, to visible spectral ranges, providing efficient EM interference (EMI) shielding [8.153, 154].

Borjanovich et al. studied irradiation with 2 MeV proton beams of pure poly(dimethylsiloxane) (PDMS) polymer and PDMS-detonation nanodiamond (PDMS-DND) composite with 1 wt % of DND [8.155]. Based on spectroscopic analysis of vibrational dynamics, it was concluded that structural degradation of PDMS-DND composites takes place at an order of magnitude higher fluence than for pure PDMS, indicating the potential of using DND-based polymer composites for application in high-radiation environments. The appearance of strong photoluminescence following irradiation

was more pronounced for PDMS-DND composites as compared with pure PDMS. Gupta et al. reported a decrease of damage of single-walled carbon nanotubes (SWCNT) by gamma irradiation when they were mixed with nanodiamond particles, providing a healing effect to SWCNT (possibly by charge transfer and dangling-bond formation and passivation) [8.156].

Several nanoadditives can be incorporated into a matrix simultaneously. Formation of ND/carbon nanotube (CNT) composites produced by codeposition of CNT and ND from a suspension was demonstrated [8.149, 150]. At certain ND/CNT weight ratios, it was possible to form large-area ND/CNT films that adhered strongly to a substrate with uniformly distributed multi-walled carbon nanotubes (MWCNTs) within a ND matrix. Nanodiamond particles were also used to disperse carbon nanotubes, allowing the formation of their stable colloidal suspensions. It was demonstrated that NDs stabilize CNTs in organic solutions that are commonly used for polymer films, coatings, and composites. Thus, the development of nanocomposites may be facilitated with the addition of NDs that serve as both a dispersive and filler material. It was demonstrated that a urethane film with added NDs showed greater dispersivity of CNTs as compared with the CNT-containing film without NDs [8.150]. Prasad et al. fabricated polyvinyl alcohol-based composites with simultaneous addition of CNT and ND and observed a synergistic effect with a 400% increase in stiffness and hardness of the resulting composites, as compared with those obtained with single nanocarbon reinforcements [8.157].

Addition of DND to polymers provides an increase in their mechanical strength, wear resistance, and heat-ageing resistance [8.62, 158]. Highly effective coatings based on incorporation of DND into fluoroelastomers and polysiloxanes have been developed, and the elastic strengths of rubbers based on polyisoprene, butadiene-styrene, butadiene-nitrile, and natural rubbers were considerably improved; for example, fluoroelastomers filled with DND particles showed an increase in the tensile modulus at 100% elongation (from 280% to 480%) and in the conditional rupture strength (from 8.5 MPa to 92 MPa and from 15.7 MPa to 173 MPa, respectively). According to [8.62], addition of DND into the rubbers decreases attrition wear by an average of 3–5 times and increases rupture strength by 30%. Based upon experiments conducted on several polymer materials [poly(methyl methacrylate), benzocyclobutene, polyimide] with 1–2% by mass of nanodiamond particles incorporated, the thermal stability of the materials increased by at least 30 °C [8.152].

In the most recent publications, incorporation of octadecylamine-functionalized nanodiamond into a biodegradable polymer, poly(L-lactic acid) (PLLA), intended for a bone scaffold material application, resulted in a significant increase in hardness and Young's modulus of the composites [8.159]. Addition of 10 wt % of ND-ODA (ODA – octadecylamine) resulted in a more than 200% increase in Young's modulus and 800% increase in hardness, bringing the nanocomposite properties close to those of human cortical bone. *Neitzel et al.* studied the mechanical and thermal properties of ND-epoxy composites at high content of ND [8.160]. Composites with 25 vol % ND showed an increase in Young's modulus (up to 470%) and hardness (up to 300%) as compared with neat epoxy. Significant increases in the scratch resistance and thermal conductivity of the composites were observed as well.

However, addition of nanofillers into a matrix does not necessarily produce a positive effect. *Comet et al.* [8.161] reported an attempt to enclose diamond nanoparticles produced by detonation into a Kevlar matrix (40 wt % diamond). The hydrogen interactions between carboxylic groups on the ND surface and the amide groups of Kevlar destroyed the *rod-like* structure and the classical three-dimensional organization of this polymer, reducing the macroscopic hardness of Kevlar doped by nanodiamonds by approximately a factor of two as compared with pure Kevlar.

Electrochemical deposition of DND together with metals using standard galvanic equipment has been demonstrated to be beneficial in a variety of applications for coatings of components of transportation units, tools for electronics, electrical engineering, medicine, and the watch and jewelry industry [8.158]. The advantages of adding DND to galvanic coatings include increases in wear resistance (2–13 times depending on the metal) and microhardness (maybe up to 2 times depending on the metal), an increase in corrosion resistance (2–6 times depending on the metal), a decrease in porosity (pores can be completely eliminated depending on the metal), a significant decrease of friction coefficient, considerable improvement of adhesion and cohesion, and high throwing power of electrolyte. According to reports [8.158], the service life of products is increased by 2–10 times, even when the coating thickness is decreased by a factor of 2–3. The strengthening effect is observed for coatings of many metals, including silver, gold, and platinum. In particular, DND is most widely used in strengthening chromium coatings deposited using an electrolytic process. In this process, DND-containing additives are added to the

chrome-plating electrolyte without any modification of the standard production line. Such coatings increase by a few times the operating life of molds, high-precision bearing surfaces, and other similar components [8.158]. Interestingly, it was recently demonstrated that the best result in terms of the microhardness for coatings prepared by the hard chromium plating method has been achieved using Nanoamando, i.e., nanodiamond particles deagglomerated to individual primary particles [8.162].

A different approach for production of DND-metal matrix composites was reported by *Nunes et al.*, who suggested a novel material design for nuclear fusion reactors based on Cu-diamond and W-diamond nanocomposites [8.163]. The proposed design involves the production of W/W-diamond/Cu-diamond/Cu functionally graded material. W, W-diamond, Cu-diamond, and Cu nanostructured composite powders were produced independently by mechanical alloying and subsequently consolidated/welded through spark plasma sintering.

A wide variety of nanomaterials in powder and colloidal forms have emerged as potential antifriction and antiwear additives to different classes of base lubricants [8.164]. Detonation nanodiamonds with 4–5 nm primary particle size and spherical shape seem to be among the most promising candidates as additives to such lubricants. Until recently, detonation soot, which is a mixture of graphite and nanodiamond particles, has been the predominant material of this class used as an additive to lubricants [8.165]. It was assumed that the combination of nanodiamond and the graphite phase is beneficial since graphite on its own has lubricating properties, while DND contributes by polishing of asperities on friction surfaces and thus reducing friction. Concerns regarding use of DND alone without a protective sp^2 shell were related to the abrasive nature of diamond powder. To a large extent the absence of positive results on using purified DND in lubricant applications was related to the fact that until recently DND was available only as a polydispersed material. However, studies by *Ivanov et al.* [8.166–168] demonstrated successful application of purified DND for enhanced tribological performance of greases and oils when used as synergistic compositions with other additives. Specifically, *Ivanov et al.* demonstrated that a combination of DND with ultradispersed polytetrafluoroethylene (PTFE) particles provides excellent lubrication properties in mineral oils of class I and greases, well exceeding those for soot and when using PTFE additives alone [8.166]. Besides 90% improvement in friction coefficient and 100% decrease in a wear spot,

extreme pressure to failure was increased up to 7 times for poly- α -olefin oil-based compositions [8.167, 168].

8.5.3 Biomedical Applications

The toxicity of particles on the nanoscale depends upon many factors, including particle size, surface chemical groups, shape, and hydrophilicity [8.169–172]. The physicochemical properties of nanodiamonds for biomedical applications have been outlined [8.64]. Diamond particles consist of a stable, nonreactive, diamond core that is biologically compatible and nonreactive. On the other hand, more commonly used nanoparticles such as quantum dots have a toxic core, so they are modified, for example, with silica coatings, to prevent toxicity. One potential route for nanodiamond toxicity is the lack of biological clearance [8.159, 173], when their particle size is too large, for example. Also, the advantageous hydrophilic property of NDs can cause a toxicological response since NDs are likely to interact with biomolecules, which may also prevent biological clearance. In addition, surface functional groups that aid in the hydrophilicity of DNDs may chemically react with or bind biological targets, or cause ND agglomeration; these reactions may be detrimental to biomolecules or biological processing. Furthermore, the surface chemistry may produce destructive chemical species, such as reactive oxygen species [8.174], which would be biologically harmful. Postprocessing is aimed at removing harmful species, such as metallic and amorphous carbon impurities, by treating DNDs with HCl and other acids, for example. On the other hand, HPHT NDs are produced with fewer impurities, so less extensive postprocessing is needed. Chemical reactions on the surface of NDs are aimed at functionality and biocompatibility; for example, the chemical modification of ND surfaces with polymeric coatings [8.175] is expected to minimize surface binding of nontargeted biological entities such as proteins, nucleic acids, cells, etc. The chemistry of DNDs is rapidly becoming more sophisticated; thus, only time is required before they are widely used in biomedical applications.

NDs have been evaluated for cytotoxicity both in vitro and in vivo. Biocompatibility studies of nanodiamonds have been summarized [8.64]. Briefly, there are a number of in vitro assays to assess cell health after exposure to nanoparticles; for example, DNDs were found to be noncytotoxic in a variety of different cell lines using in vitro approaches, including morphological imaging, cell viability, and reactive oxygen species production; it was found that DNDs do not illicit inflam-

mation or cytotoxic responses by the cell [8.8, 9, 64]. In addition to the lack of inflammation, DNA fragmentation assays also showed that DNDs were not cytotoxic [8.91, 131]. Similarly, fluorescent carboxylated HPHT NDs (FND) do not reduce cell viability or protein expression in lung cells [8.176]. Imaging studies of fluorescently labeled DNDs detailed the uptake of particles by cells, remaining stable through translocations of endosomes and lysosomes without affecting cell viability [8.144].

The primary particles of DNDs are small (4–5 nm) and round, so would be expected to have good biological clearance. In one recent study, DND agglomerates that were broken down to the primary particles did exhibit whole-body clearance in mice [8.119]. Conversely, HPHT NDs are usually modified to decrease their size and made round instead of their naturally crystalline shape. On intravenous injection into mice, larger, 50 nm HPHT NDs that were not milled for spherical shape (Advapowder Co., China), and appeared crystalline with sharp edges and side, were found to be retained in the liver, spleen, and lung after 28 days [8.173]. HPHT NDs, 100 nm size but from a different source (Element Six), were fed or microinjected with fluorescently enhanced NDs (FND) [8.177] to worms (*Caenorhabditis elegans*). The NDs did not appear to affect their stress, reproductivity, or longevity. Only FNDs coated with dextran or bovine serum albumin (BSA) are taken up by intestinal cells, while tracking of the FNDs could be done continuously and through the next generation [8.178].

Studies by Dolmatov have shown that DNDs prolonged the life and improved the health of mice, dogs, and humans with cancer, presumably by adsorption of free radicals as well as other toxins [8.158]. A summary of in vivo studies with DNDs has been tabulated [8.64]. In vivo studies have shown limited toxicity; however, safety in humans cannot be determined from animal models.

Specific Applications

Use of NDs as substrates for delivery has been investigated for vaccine and drug delivery, immunoassays, antimicrobial agents, and biosensor development. The solid platform of NDs has been used for drug delivery of the chemotherapeutic drug doxorubicin (Dox), which showed good activity, while limiting the toxicity of the drug. More recently, Li et al. showed that DNDs could be used as carriers for the chemotherapeutic drug 10-hydroxycamptothecin; its release can be effected by lowering the pH of the media, while this combination

demonstrated that the complex has higher efficacy than the drug alone [8.132].

The study of drug delivery by NDs using Dox is extensive. Physisorption of Dox on carboxylated DNDs was achieved by electrostatics that could be released in the presence of excess salt [8.91]. In addition, a ND/Dox polymeric patch system was developed to allow for site-specific delivery of Dox, being shown to be biocompatible and biofunctional [8.131]. Furthermore, the most recent work by Ho et al. has shown that the ND/Dox complex is safe in mice and allows for slow release of Dox, increasing the blood circulation half-life by tenfold while decreasing the toxicity. Toxicity was monitored by a decrease in the inflammatory response, as compared with high doses of Dox delivered alone. DND transport was monitored through the kidneys, spleen, and liver; whole-body clearance was found for the smaller ND particles ($\approx 4\text{--}5\text{ nm}$) [8.119].

HPHT NDs are effective substrates for antigen delivery of mussel adhesive protein, a protein for which it is difficult to illicit an immune response. Thus, use of NDs may allow development of a surgical adhesive or a corrosion inhibitor [8.179]. In addition, DNDs are able to complex and stabilize an antibody (transforming growth factor), preserving the antibody's activity, while releasing it from its nanoparticle carrier in a physiological environment [8.180].

For gene or vaccine delivery, NDs have the ability to stabilize DNA without causing damage, as compared with traditionally used heavy-metal nanoparticles. The usefulness of DND as a general, robust solid-phase support was demonstrated in experiments using the Bio-Rad PDS-1000/He instrument for the delivery of bioactive molecules to yeast, fall armyworms, and bananas [8.134]. In comparison with other cell delivery methods (not including the nanofountain detailed below), biolistic delivery can target cells with bioactive molecules over a wide range of velocities and distances. As compared with gold nanoparticles, NDs as biolistic delivery platforms are beneficial because they are less toxic, nonexplosive, nonvolatile, water soluble, and less costly. One example included use of ND-assisted ballistic delivery of diphenylcyclopropenone, an ethylene antagonist, which was used to prevent ripening of bananas. In a second example, DNA was delivered to bacterial cells using the same method [8.134]. The immobilization of DNA onto NDs led to its use in plasmid delivery via ballistic bombardment.

DNDs may be used for therapeutic delivery of silencing RNA (siRNA), which is expected to be beneficial for knocking out deleterious genes. The polyanion RNA

was electrostatically bound to the DND carrier using a polycationic mediator, polyethylenimine. As compared with the typically used liposomal siRNA delivery vehicle, the DND hybrid complex as a whole was capable of a similar cell transfection efficiency causing gene knockdown of green fluorescent protein, while being nearly noncytotoxic, unlike liposomal siRNA delivery vehicles [8.135].

DNDs can also be used for gene delivery due to the stabilization of a DND/plasmid complex, which also promotes transfection efficiency. In this case, methacrylate cationic polymer brushes, widely used to mediate gene delivery, were grafted onto DNDs by atom-transfer radical polymerization. These particles were found to be good carriers for plasmid DNA, preventing enzymatic degradation of the plasmid, while effectively transfecting cells and allowing for imaging of the innate fluorescence of DNDs by scanning confocal microscopy [8.136].

Although ND can be used as a platform for therapeutics, its ease of chemical modification also provides controlled design of chemical therapies; For example, the development of a ND–gadolinium complex was found useful for magnetic resonance imaging that increases the image contrast by tenfold as compared with Gd used alone [8.181].

DND in Healthcare Products

Nanodiamonds are also considered for cosmetics and healthcare applications due to their ability to bond with biological materials, improving the durability and robustness of a composition. The Environmental Working Group lists a number of cosmetic products currently on the market containing diamond powder, including nail polishes, nail treatments, anti-aging formulation, and facial cleanser. The diamond powder is listed in the formulations as a material with low hazard score (1 out of 10); For example, Sung et al. hypothesize that nanodiamonds dispersed in a biologically acceptable carrier and bonded with biological materials may offer improvement when applied in various cosmetics and cleansers [8.182]. As cleansers, NDs have specifically been studied for antimicrobial and antifungal properties. For antimicrobial applications, NDs loaded with lysozyme have been evaluated since this enzyme cleaves bacterial cell walls. The adsorption capacity of carboxylated HPHT NDs was used to make a ND/lysozyme complex based upon electrostatics. The activity of the lysozyme was found to be 60% with ND surface coverage of 50% [8.183], while Raman mapping showed that the enzyme retained its func-

tionality [8.184]. Thus, NDs can act as a solid-phase platform for lysozyme to provide a reusable antimicrobial substrate to treat surfaces or solutions, for example.

Another potential application of nanodiamonds in healthcare products is protection from ultraviolet radiation (UVR) [8.185]. DND has high refractive index (≈ 2.4) and efficiently scatters light. Attenuation of UVR by DND can be enhanced due to the absorption by the sp^2 carbons on the DND surface. In addition, many lattice defects and impurities found in natural and synthetic diamonds absorb UVR [8.186], contributing to the radiation attenuation. DND is a very attractive candidate as a physical sunscreen due to its biocompatible, nontoxic properties and excellent physical strength.

As a seed material for CVD diamond growth, DND particles play an important role in the development of medical implants [8.187, 188]. Seeding with DND allows coatings with small grain size and, therefore, smooth surfaces that are important for medical implant applications.

Carbon- and clay-containing adsorbents are commonly used to bind ingested toxins in medical and pharmacological industries. However, their use can be potentially fatal to both animals and humans [8.189, 190, 190, 191]. As a remedy after accidental ingestion of mycotoxins, which are low-molecular-weight byproducts of mold growth, enterosorbents are used to specifically bind the toxins while remaining biocompatible, well dispersed in aqueous solution, and stable for transportation and administration. Currently, enterosorbents that are safe and practical are not readily available [8.191]. DNDs are considered as potential enterosorbents for binding a group of mycotoxins called aflatoxins, because of their high biocompatibility, small size, large surface area, rich surface chemistry, inexpensive production, and variety of available samples. A positive zeta potential is the main property that contributes to the greatest aflatoxin adsorption onto DNDs [8.192]. At 0.1 wt % concentration of DND in water slurries, the two samples with adsorptive capacities of over 100 mg of aflatoxin/kg of ND were purified detonation NDs, being 185 and 300 nm in size with surface charges of +47 and +18, respectively. It would be desirable to further control the ND surface chemistry, determine their optimal concentrations, and reduce the size of the ND aggregates useful for applications in low-pH environments such as the stomach.

Biosensors and Biochips

DNDs may be used as a solid-phase capture probe for physisorption of biological molecules. Early re-

search showed that DND nanoparticles are capable of adsorbing recombinant apoobelin and luciferase proteins [8.193]. It has been found that DNDs have tenfold greater binding capacity for the protein lysozyme as compared with traditional chromatographic substrate, nanosilica, which is probably due to the greater surface area of porous nanodiamond [8.194].

Bioactive substrates or biosensors can be fabricated by collection of DNDs by electrophoresis; For example, it was demonstrated that collection of DND onto a support is possible by electrophoresis. In this application, biotinylated nanodiamond conjugate probe (ND-biotin) was used to capture its target (streptavidin) [8.110]. In a more sophisticated and precise approach for ND array patterning, the application of direct-write nanopatterning was used with a DND ink, whereby the DND was conjugated to a fluorophore. This nanofountain instrument demonstrated that it is possible to insert DND probes into single cells, thus paving the way for systematic studies of drug or DNA therapeutics in biomedicine. It could also be used to create DND-probe-based arrays for biochip sensors [8.195].

As an ultimate platform, DND agglomerated particles are capable of forming ordered assemblies by centrifugation. With a narrow size fraction of DND (≈ 150 nm), centrifugation causes ordering of the particles along the centrifuge tube. At the top, the interparticle distance is large, resulting in a red color, and at the bottom the interparticle spacing is smallest, causing a blue color (Fig. 8.13). This results in a rainbow of colors along the length of an Eppendorf tube. Analogous to these rainbows, further centrifugation caused a three-dimensional crystallization of similar interparticle spacing for a particular color, producing photonic crystals that were millimeters in size and very bright [8.151]. These ordered DND particle assemblies may have applications in biodiagnostics, providing a colorimetric signal for the presence or absence of targeted biomolecules. In addition, their robust chemical and physical properties also may be exploited to advance the biosensor field [8.64].

8.5.4 Nanodiamonds for Seeding

Diamond film growth by chemical vapor deposition (CVD) has been under investigation since before 1975 [8.196]. One aspect of this research is the use of diamond seed crystals to increase the rate of growth. The use of HPHT nanodiamonds as seeds began in the late 1990s, but their large size produced nonuniformity in the diamond film. In 2003, seeding from nanodi-

amonds of detonation origin was shown to produce superior films. Use of **DNDs** as the seeding material has continued since this time [8.197]. Recently, laboratories that grow diamond films have begun procuring **DND** slurries from facilities that specialize in **DND** technologies, and these partnerships have greatly improved the development of **DND** seeding slurries.

To produce uniform diamond films, the **DND** must be of small particle size and evenly distributed on the substrate of interest. To achieve this goal, deagglomeration of particles is required, bead-milling is often used to break down primary particle agglomerates [8.90], and a colloidal suspension of the **DND** particles is needed. In the last few years, advances in **DND** deagglomeration and fractionation have produced seeding slurries with consistent properties. Williams et al. have developed methods for improving the nucleation density of nanocrystalline diamond film growth using bead-milled **DND** that is processed to form stable aqueous colloidal solutions of primary particles. This colloid was applied to various substrates to yield a high density of individually spaced diamond nanoparticles (greater than 10^{11} cm^{-2}) [8.187, 188].

As a cost-effective, commercial product, **DND** seeding slurries are initially formed by centrifugal fractionation [8.100], which eliminates sp^2 formation and zirconia impurities produced by milling. It has been found that the most effective solvent for producing colloidal **DND** suspensions for seeding is dimethylsulfoxide (**DMSO**) [8.198] (Fig. 8.14a). The most striking

properties of **DMSO** are best illustrated using unfractionated **DND Standard** product (with 250 nm agglomerate sizes), which contains 1.4 wt % of incombustible metallic impurities. (It should be noted that only purified **DND** is used for commercial seeding applications.) **DMSO** produces colloidal suspensions of Standard **DND**, whereas suspensions in water readily sediment. For **DND** slurries in **DMSO**, addition of methanol produces a colloidal solution that is readily fractionated. This is surprising since **DND** in methanol alone readily sediments. Centrifugal fractionation of Standard **DND** is efficient using high concentrations of **DND** (3% w/v) in **DMSO** and effectively produces small particles (48 nm average size) at high concentration (0.9% w/v). Thus, centrifugation alone can be used to isolate small **DNDs**, while ball-milling requires purification steps. For our purified and fractionated 100 nm **DND** product, superior results are obtained starting with higher **DND** concentrations (up to 3.5%) for the centrifugation step, producing particles that are smaller (25 nm) and at higher concentrations ($\approx 0.5\%$). An example of successful seeding is shown in Fig. 8.14b. There exists one caveat, however, in that only **DNDs** with positive zeta potentials are stable in **DMSO**. Thus, negatively charged or air-treated **DNDs** cannot be processed with this solvent. As compared with water suspensions, **DMSO** allows for smaller, more concentrated, more stable dispersions of **DNDs** [8.199].

DMSO can also be useful in retaining the **DND** size after removing the solvent to produce powders. **DNDs**

Fig. 8.14a–d Photographs showing detonation nanodiamond seeding. The colloidal solutions for seeding are transparent for high concentrations (left) and lower concentrations (right) (a). Scanning electron microscopy (SEM) image of seeding on a silicon substrate using **ND opal** seeds (b). SEM images of seeding carried out on highly structured substrates such as silicon field tips (c) and carbon nanotubes (d)

dried from DMSO retain their small size when reconstituted in DMSO or in water, whereas DNDs dried from water result in agglomerated particles that are approximately twice as large in diameter. In addition, a 10 vol. % volume fraction of DMSO added to water before drying prevented agglomeration [8.199].

Starting with purified DNDs, a rapid collection process for small, pure DND particles is possible using DNDs in DMSO suspensions. However, seeding with alcohols allows for rapid drying of substrates, so the addition of alcohols to the DMSO seeding slurry has proven successful. The effectiveness of seeding on Si was compared by varying:

1. The fractionation solvent (DMSO or DMSO/MeOH)
2. The solvent composition of the seeding slurry solution (DMSO or DMSO/MeOH)
3. The concentration of DND in the slurry.

The most successful seeding, which consists of discretely spaced, small DND particles (some are 5 nm), was obtained from polydispersed DNDs that are (1) fractionated from DMSO, and (2) seeded by sonication using DMSO/MeOH slurries in a 1 : 1 ratio (Fig. 8.14b) [8.199].

DND seeding is possible on different materials, such as metals, and on highly structured objects, including carbon nanotubes and silicon tips (Fig. 8.14c,d) [8.199]. Thus DND, as a seed material for CVD diamond growth, is important for many applications, from ma-

chines to medical implants [8.187, 188]. Different types of carbon coatings [among them diamond-like carbon (DLC) and diamond] deposited on the surface of implants increase implant biocompatibility and hemocompatibility, and serve the role of a barrier against corrosion [8.200]. Nanocrystalline (NC) and ultrananocrystalline diamond (UNCD) coatings on suitable substrates are promising materials for medical orthopedic implants, for example, hip and knee joint implants [8.201], and for coating of certain components of artificial heart valves [8.202, 203] due to their extremely high chemical inertness, surface smoothness, and good adhesion of the coatings to the substrate. These films are able to coat complex geometrical shapes with good conformal accuracy and with smooth surfaces to produce hermetic bioinert protective coatings, or to provide surfaces for cell grafting through appropriate functionalization. However, recent studies have shown that diamond powders are not bioinactive at the molecular level; they affect cellular gene expression and inhibit stress, such as oxidative, cellular, and genotoxic [8.204]. UNCD is a more suitable material than silicon for fabrication of biological microelectromechanical systems (bioMEMS); For example, in the case of a Si microchip implantable in the eye as the main component of an artificial retina to restore sight to people blinded by retina degeneration, Si cannot survive long-term implantation, while UNCD bioinert encapsulation can successfully replace the Si microchip implantation in the eye [8.205].

8.6 Future Directions of Production and Applications

Compared with many other nanomaterials, DND produced by detonation of explosives is relatively expensive since it has not experienced production scale-up to large volumes. As with any market, a high price is a factor that will inhibit widespread use in the marketplace. Even at the current purity and particle size, particularly for bulk manufacturing, with a 50% reduction in price the demand for DND would increase dramatically [8.206]. Recent advances in separation and fractionation methods of DNDs have led to the current availability of 50, 20, and 5 nm particle sizes. As the material meets the demands of specific uses, the increased production volume of these smaller-sized fractions will open up new markets and expand existing ones; For example, the recent availability of single-digit ND particles, produced by detonation of explosives

in kilogram quantities [8.4], has opened broad perspectives for the application of ND in composites and nanolubricants. Other prospective applications include the use of DND in polymers, sunscreens, and galvanic coatings. Although new technologies are providing the means to increase the production of small-sized fractions in larger volumes, the method of production of the initial soot has largely remained the same for the past 30 years. Other methods of ND synthesis, such as laser-assisted synthesis [8.80], are intended to be useful for large-scale production. In addition, breaking of HPHT diamond into sub-10 nm particles is an important breakthrough for applications in quantum optics and luminescent markers. Both approaches, DND deagglomeration and HPHT ND milling, require further development of inexpensive processing meth-

ods so that single-digit NDs will be affordable for large-scale production and applications. Furthermore, production of electroconductive (i.e., boron-doped) nanodiamond particles during their synthesis would be very useful for broad applications in high-surface-area carbon electrode materials in electroanalysis and energy storage applications. If inexpensive methods of HPHT ND milling are developed, grinding of electrically conductive HPHT diamond will be advantageous also.

Nanodiamond's large and reactive surface area enables a broad range of modifications without compromising its superior chemically inert, physically strong diamond core. Recent achievements in the functionalization of NDs have led to a whole new range of applications, and this topic remains an object of intense research. Thus, it can be concluded that a *golden age* of diamond particles has begun, which will lead us to rapid, widespread use in both commodity products and brilliant materials of the future.

Pratap Kumar Deheri, Singapore, Singapore
Raju V. Ramanujan, Singapore, Singapore

Noble Metal

9. Noble Metal Nanoparticles

Theruvakkattil S. Sreeprasad, Thalappil Pradeep

Noble metal nanoparticles in general and their gold and silver analogs in particular are attracting huge interest from the scientific community owing to their fabulous properties and diversity of applications. Mankind has been fascinated by gold and silver since prehistoric times, and applications of their nanoparticles have attracted attention for millennia, although understanding phenomena at the nanoscale is very recent. Nanoscale analogs are being explored due to their unusual functional attributes quite unlike the bulk. As research in this area moves forward, scientists are discovering novel application possibilities. Tunability of properties by varying size, shape, composition, or local environment presents them with unusual capabilities. By manipulating the chemical composition of the materials at the nanoscale, their electrical, chemical, optical, and other properties can be manipulated precisely. In this chapter, an overview of their history, diversity, strategies of synthesis, and optical properties is presented. The specialized methods employed for synthesis of anisotropic nanosystems are also discussed. Approaches to modulate the properties of these systems postsynthetically either through chemical reactions or by the formation of superstructures via assembly are also covered. Methodologies for fabricating functionalized nanomaterials are also discussed. Various proposed applications of such materials are pointed out. A glimpse into a newly emerging category of noble metal nanosystems called quantum clusters is also given.

Noble metals are those metals which are resistant to corrosion and oxidation in moist air. The list contains ruthenium, rhodium, palladium, silver, osmium, iridium, platinum, and gold, in order of atomic number. Many of them are also precious as they are of poor abundance in the Earth's crust. Noble metal nanoparticles (NPs), especially of gold (Au) and silver (Ag), have been intensely explored by the scientific community owing to their spectacular properties. The *noble*

nature of these NPs compared with other NPs, for example, transition metal NPs such as iron, nickel, or cobalt, as well as their lesser cytotoxicity make them attractive candidates for biological and environmental applications. A large proportion of the study of noble metal NPs is done with Au and Ag NPs. Therefore, Au and Ag NPs can be taken as examples to demonstrate the relevance and diversity of the area of NPs in general.

9.1 Historical Perspective of Gold and Silver NPs

From time immemorial, three metals, namely gold, silver, and copper, were used extensively by mankind. In fact, it is certain that these were the metals first used by human beings, since they are found in the native state. Even before the invention of gold coins in Egypt around 3400 BC, these metals were used as primitive money, hence the name *coinage metals*. The origin of the names *gold* and *silver* has long history. Different words are used in different languages to represent gold. Most of them simply mean *yellow (metal)*, which comes from its appearance; for example, the Latin name *aurum* means yellow. This word is believed to have been coined from the ancient Roman word *aurora* or *ausosa*, meaning morning glow. The word is said to have its origin in the Sanskrit word *hari*, meaning *yellow*. In Slavic languages, gold was referred to as *złoto* (*zlato*), having connections with the Indo-European word *sol* (sun). The present-day name *gold* is believed to have Germanic origin (*goud* in Dutch). The root of the word *gold* is believed to be from *gelwa*, meaning again yellow, which is connected to the Sanskrit word *jval*, meaning *to shine*. Hence, the word *gold* really means *the yellow shining metal*. Silver also has a rich history and it is also known by different names. It has different but very similar names in Dutch (*zilver*), German (*Silber*), and Anglo-Saxon (*seolfor*). In Greek, silver is known as *argyros* and in Latin as *argentum*, which in turn are closely related. The Italian (*argento*) and French (*argent*) names are also similar. However, the Spanish use a totally different name for silver: *plata*.

Gold and silver NPs have a rich history in science, where they were used for both esthetic and medicinal purposes [9.1]. A mixture of gold salts with molten glass was used by medieval artisans to produce tiny gold colloids having a rich ruby color, and their varieties were exploited for coloration of glass, ceramics, and pottery. The great alchemist and founder of mod-

ern medicine, Paracelsus (1493–1541), developed many highly successful treatments from metallic minerals, including gold. In China, people cook their rice with a gold coin in order to help replenish gold in their bodies. Colloidal gold has been incorporated into glasses and vases to give them color. The oldest of these is the fourth century AD Lycurgus cup made by the Romans (one piece is kept in the British Museum in London) (Fig. 9.1). The cup appears red in transmitted light (if a light source is held within the cup) and appears green in reflected light (if the light source is outside). Modern chemical analysis shows that the glass is not much different from that used today. However, it contains very small amounts of gold (about 40 ppm) and silver (about 300 ppm) in the form of mixed Au-Ag NPs of approximately 70 nm diameter. *Purple of Cassius*, a pink pigment commonly used in the seventeenth century, is also now known to be a combination of gold particles and tin dioxide.

The Egyptians used gold for mental, bodily, and spiritual purification [9.2], and the medicinal use of gold can be traced back to China in 2500 BC. In ancient times, Egyptians used gold in dentistry as well. In the Indian medical system called *Ayurveda*, gold is used in several preparations. One popular preparation is called *Saraswatharishtam*, prescribed for memory enhancement. Gold is also added in certain medicinal preparations for babies, in order to enhance their mental capability. All these preparations use finely ground gold along with herbs.

The curative power of gold is well documented from antiquity. Until the Middle Ages, gold was used as a cure for various diseases such as heart and venereal problems, dysentery, epilepsy, and tumors, as documented in a book written by Francisci Antonii in 1618 [9.1]. The use of *soluble gold* for diagnosis of syphilis is also documented [9.1]. In his book of 1676,

Fig. 9.1 (a) Michael Faraday (after [9.3]). (b) Faraday's gold preserved at the Royal Institution of Great Britain (after [9.4]). (c,d) The Lycurgus cup made from glass appears red in transmitted light and green in reflected light (after [9.5]). (e) The 70 nm Au-Ag alloy NPs found in the glass of the Lycurgus cup, as seen in a transmission electron micrograph (after [9.5])

Johann Kunckels mentioned a form of gold which he addressed as *drinkable gold that contains metallic gold in a neutral, slightly pink solution that exerts curative properties for several diseases* [9.1]. In this book, he even foresaw the possibility of the existence of gold in a form that is not visible to the human eye. It was also reported in 1718 by Hans Heinrich that the stability of *drinkable gold* can be increased by a special combination with boiled starch [9.1].

During this period, gold was used for coloring fabrics as well. In 1794 Mrs. Fuhlame reported that she had dyed silk with colloidal gold, which is documented in her book *An Essay on Combustion with a View to a New Art of Dying and Painting*. The different colors exhibited by different *drinkable gold preparations* were explained by Jeremias Benjamin Richters in 1818 [9.1]. He hypothesized that *pink or purple solutions contain*

gold in the finest degree of subdivision, whereas yellow solutions are found when these fine particles have aggregated [9.1].

Systematic chemical synthesis of colloidal NPs was pioneered by Michael Faraday in 1857, when he observed the formation of a pure form of deep-red-colored colloidal gold by the reduction of an aqueous solution of chloroaurate (AuCl_4^-) using phosphorus in CS_2 in a two-phase system [9.6] (the word *colloid* itself was nonexistent at the time of Faraday's work). This is considered to have been a major step in the development of nanotechnology. He found that colloidal gold had special optical and electrical properties. In this study, he also investigated the optical properties of thin films prepared from dried colloidal solutions. He observed a reversible color change from bluish-purple to green upon pressurizing the films. In 1861, *Graham* coined the word *colloid* from the French word *colle* [9.7]. Following Faraday, a large number of experimental methods have been reported for synthesis of gold NPs (GNPs). This is dealt with in a separate section.

Similar to gold, silver has also been used for thousands of years in various fields. As explained earlier, it is Au-Ag NPs which are responsible for the color of the Lycurgus cup. However, the major use of silver historically was in the medicinal field and as an antimicrobial/disinfectant agent. Silver vessels were used to keep water and other liquids fresh by the Greeks [9.8]. The writings of *Herodotus*, the Greek philosopher and historian, date the use of silver to before the birth of Christ [9.9]. Silver urns were used for storage of wine to prevent spoilage in the Roman Empire. A similar use of silver is mentioned in ancient Egyptian writings also. Although most ancient civilizations were not fully aware of the antibacterial properties of silver, it was widely accepted that addition of silver to water would increase clarity, reduce odor, and improve the taste as well [9.10]. In ancient civilizations (especially the Greek and Roman Empires), Ag was used for various applications because of its well-known medical, preservative, and restorative powers [9.8, 10]. The germicidal power of silver was also known during these times [9.11]. Before modern germicides and antibiotics were discovered, the old civilizations understood that disease-causing pathogens would not survive in the presence of silver. Hence, silver was used in dishware, drinking vessels, and eating utensils [9.11]. Rich families of those periods stored and ate their food from silver vessels to prevent bacteria from growing. This is perhaps the reason for the phrase, *born with a silver spoon*, indicating traditional wealth. Vikings had knowledge

of the antialgal effects of silver. They applied strings of silver and copper below the water-line on the hull of their ships to prevent growth of algae and barnacles. The same methodology is used on modern ships as well [9.12].

Hippocrates, the father of modern medicine, promoted the use of silver by writing about the beneficial healing and antidisease properties of silver in his book [9.13]; he also recommended the use of finely powdered silver formulations for various ailment conditions such as ulcers and wounds [9.14]. Alexander the Great was advised by Aristotle to boil and store water in silver vessels to eradicate waterborne diseases [9.15]. Ancient Indian civilizations also had knowledge of the medicinal powers of silver. In Ayurvedic medicine, silver was used (in small amounts) as a tonic and rejuvenating agent for patients incapacitated by age or disease. Silver was also used as an eyedrop for ophthalmic problems [9.16], for various infections [9.17], and sometimes internally for diseases such as gonorrhea, epilepsy, common cold, and tropical sprue [9.11, 18]. Colloidal silver preparations (CSP) were used to treat or prevent gonorrhea and gonorrheal conjunctivitis [9.19]. It was also used in pure silver tongue scrapers as part of dental maintenance and for other oral disease conditions. Silver was widely used for the treatment of heart problems, blood purification, and other conditions, especially in the Middle East. Silver needles have been used for acupuncture by physicians of Chinese medicine over the years.

Silver also found applications in many other medical therapies and devices, including bone prostheses, ophthalmic surgery, treatments for venereal disease, and veterinary medicine [9.10]. The use of silver pins to fuse bones, silver wire to suture wounds, silver powder on ulcerations, and silver foil to protect wounds against infection was reported by ancient surgeons. In Egypt, skeletons where silver pins were used to repair bones via surgical procedures were found to support this [9.15]. As early as the late thirteenth century, it is reported that Lanfranc utilized silver tubes for introduction of food beyond fistula [9.20]. However, Paracelsus is credited to be the pioneer of the use of metals for medical applications. In his hermetic and alchemical writings, he associated silver with the development of brain activities. In 1617 Fabricius of Aquapendente, used a small silver tube to feed patients suffering from tetanus [9.21]. In 1884, Crede, a German obstetrician, popularized administering 1% silver nitrate solution to newborns to prevent ophthalmia neonatorum [9.22, 23]. It is also documented that he even

used finely divided silver powder also for medical applications in 1896, which can be considered as the first proper medicinal use of colloidal silver [9.24, 25]. It is also documented that, during the mid-nineteenth century, silver wire structures were used to reduce septic complications [9.20]. Even in the late eighteenth century, William Halsted used silver wire for hernia operations and silver foil to prevent wound-related infections [9.26]. It is documented that, during the late 1800s and early 1900s, silver was frequently used as a medicine. During ancient times, it was understood that several metal salts and compounds have strong germicidal properties. However, it was also proved that silver alone has both strong germicidal properties and low or no toxicity to humans, which increased the use of silver-based preparations. The colloidal state is known to be the most effective form among other formulations because colloidal silver does not have the caustic properties of salts (such as AgNO_3) and it also demonstrated a high level of activity at very low concentrations [9.24]. Although it was established that colloidal silver was superior in this regard, the use of silver nitrate continued for a long time [9.24].

Scientific and methodological study of the antibacterial effects of metals against bacteria and lower life forms was carried out by Ravelin (1869) and in a more detailed manner by Karl Wilhelm von Nägeli, a Swiss botanist who discovered chromosomes (he named them *cytoblasts*) [9.13]. Nägeli reported that even low concentrations (9.2×10^{-9} and 5.5×10^{-6} M) of extremely fine silver, copper, as well as other metal hydrosols have toxic effects on *Spirogyra* and *Aspergillus niger* spores, respectively. The term *oligodynamic effect* was coined by him to explain this phenomenon [9.13]. In early twentieth century the germicidal properties of colloidal silver were popularized by Henry Crookes. He even stated in his book [9.11, 24] that:

silver in the colloidal state is highly germicidal, quite harmless to humans and absolutely nontoxic. Rather than in a chemical compound, the silver in the colloidal state may be applied in a much more concentrated form, with correspondingly better results. All virus, fungus, bacterium, streptococcus, staphylococcus, and other pathogenic organisms are killed in three or four minutes upon contact. There are no side effects whatsoever from the highest concentrations.

Long before the introduction of antibiotics, colloidal silver had been known and used as a bactericide for at least 1200 years [9.15]. Also, it is reported that in

World War I, when antibiotics has not yet been discovered, silver formulations were used to prevent and treat infections, as antiseptics [9.27], as eyedrops to prevent conjunctivitis, etc. Silver compounds were used in dermatology to treat certain skin conditions, such as corns and warts [9.28]. In the early 1900s, silver foil dressings were used for wounds. These dressings were used extensively until just after World War II and were listed in the Physician's Desk Reference until 1955 [9.27]. However, with the introduction of antibiotics in the 1940s, the use of silver as an antimicrobial agent diminished. Still, silver holds an edge over antibiotics, since bacteria do not generally develop resistance to silver unless they have a very thick wall that does not absorb it [9.10].

In 1889, *Frens* and *Overbeek* [9.29] and *Lea* [9.30] accomplished a major landmark in chemistry by preparing silver colloid for the first time through reduction of silver nitrate using ferrous sulfate and consequent protection of colloidal particles with citrate ions. A huge interest in colloidal silver followed this, and a large number of researchers worked on the antibacterial properties of silver in the early twentieth century. Research work was initiated to use silver for water purification as well. In 1928, *Katadyn* of Switzerland developed a silver-impregnated ceramic gravity-fed water filter termed *Katadyn silver*. This was utilized as an antibacterial water filter in remote areas where clean water was not readily available by various agencies and militaries around the world [9.31]. In another instance, in a Federal Bureau of Investigation (FBI) declassified

document 100-93211.247 dated December 21, 1949 and declassified on September 9, 2004, the use of silver for converting sea water to fresh water is quoted. This document illustrates that during World War II the US Navy used the services of Alexander Goetz, then Associate Professor of Physics at the California Institute of Technology, for generating drinking water. The document says *he helped perfect the process for converting sea water into fresh water by the use of silverized carbon pellets* [9.32]. Throughout the twentieth century, the popularity of silver salts continued to grow and several silver-based products were also commercialized (*Katadyn*, *Argyrol*, *Movidyn*, *Tetrasil*, *Alagon*, etc.) [9.33]. Silver in the supported form was also used to disinfect water. Zero-valent silver was immobilized on activated carbon in 1966 by *Renn* for disinfection of water [9.34]. Silver has also been used in space programs since the Apollo missions to sterilize recycled water. The same practice continues, and silver ion-exchange materials are still being used in space stations and space shuttles to recycle water.

As this historical perspective illustrates, gold and silver have been used for a large number of applications in several fields. However, until the last century, most applications were restricted to their medicinal value or antimicrobial activity. Catalysis is another area where silver found application in the early twentieth century. A few examples where noble metals were used as catalysts include silver-based catalysis of methanol to formaldehyde [9.35] and ethylene to ethylene oxide [9.36].

9.2 Diverse Nanostructures

The size and shape-dependent variation in properties of matter at the nanoscale is one of the most fascinating aspects of nanoscience. Hence, various parameters which directly affect the intrinsic properties of such materials [9.37–40] must be thoroughly understood. Nanomaterials can be broadly classified into four groups depending upon the confinement: (a) zero-dimensional (0-D), (b) one-dimensional (1-D), (c) two-dimensional (2-D), and (d) three-dimensional (3-D) nanomaterials. Similarly, based on geometry, they can be classified into isotropic and anisotropic NPs.

Gold and silver nanosystems are interesting because of the diversity that they exhibit. They are found in different shapes. Spherical NPs, quantum dots, and the newest excitement in the subnano regime called *quantum clusters* are all included in isotropic

nanosystems, since they have no specific direction of growth and no difference in properties in different directions. They are generally considered to be 0-D nanosystems. However, materials of 1-D and 2-D NPs, and most 3-D nanosystems, which usually have a specific direction of growth and confinement of electronic motion along specific axes, are included in anisotropic NPs. Anisotropic NPs comprise a plethora of nanostructures such as nanorods (NRs) [9.41–43], nanowires (NWs) [9.44–46], nanotubes [9.47] (which can be collectively termed as 1-D); triangles [9.48, 49], plates and sheets [9.50, 51], ribbons or helices [9.52, 53], nanobelts [9.54, 55], nanocombs [9.56], nanorattles [9.57] etc. (belonging to 2-D), and pyramids [9.58, 59], stars [9.60, 61], flowers [9.62–65], multipods [9.66, 67], nanourchins [9.68, 69], tad-

poles [9.70, 71], nanocages [9.72, 73], nanorice [9.74, 75], nanocorn [9.76], nanoboxes [9.77, 78], nanocubes [9.79], triangular nanoframes [9.80], nanodumbbells [9.81], etc. (belonging to 3-D).

Noble metal nanosystems are attracting intense research efforts due to their diverse properties and exceptional tunability in properties. The size, surface, and shape dependence of the physical, optical, and electronic properties of anisotropic nanomaterials make them fascinating components in modern materials research. These properties of these systems are dealt with in a separate section. However, the most important step in utilizing these properties is to synthesize these materials with precise control over their size and shape. Specialized synthetic strategies are needed to make them with precise control over size and shape. These synthetic methods, at least in some cases, should have the flexibility to be expanded for possible commercial exploitation, if suitable applications are found. In this section, the most common methods used for synthesis of noble metal nanomaterials are briefly discussed.

9.2.1 Physical and Chemical Methods

General methods of synthesis can be broadly divided into two categories: physical and chemical routes. In the former approach, bulk material or constituents of the desired nanomaterial are taken and formulate systematic conditions by which nanomaterials are formed. Since the methods of synthesis start from bulk materials, they are called *top-down* approaches. This method includes the following techniques:

1. High-energy ball milling: Nanoscale powders are produced by milling bulk materials.
2. Wire explosion: Used to produce conducting nanomaterials such as metals. A sudden high current pulse is supplied resulting in an explosion.
3. Arc discharge: Alternating current (AC) or direct current (DC) arcs are used to evaporate materials.
4. Inert-gas condensation: Particle growth is achieved by condensing evaporated atoms in a matrix.
5. Laser ablation: High-energy laser to induce evaporation.
6. Ion sputtering: Impact using high energy ions (usually rare gases) cause evaporation.

By controlling the environment in which evaporation happens, we can control the composition of the resulting material. For example, if evaporation of metals occurs in the presence of oxygen, oxides can be pro-

duced. These methods can effectively manufacture large quantities of materials. However, these methods can only produce materials with large particle size variation.

In chemical methods, which will be described in more detail later, a range of techniques is used. In all of these, nanomaterials are made starting from atoms generated from ions, in solution, and are assembled to make nanomaterials. As the synthesis initiates from atoms, these methods are also called *bottom-up* approaches. Several methods come under this category:

1. Chemical reduction: Metal ions are reduced using reducing agents to create atoms.
2. Electrochemical synthesis: Electrochemical reduction or oxidation reactions.
3. Photochemical synthesis: Chemical processes assisted by light.
4. Sonochemical routes: Chemical reaction system done with the aid of ultrasound.
5. Solvothermal synthesis: Chemical processes in a closed system using solvents at lower temperatures.
6. Interfacial synthesis: An organic-aqueous interface is created to make nanomaterials.
7. Micelles and microemulsions: Producing nanomaterials by using oil-in-water or water-in-oil emulsions, or cavities of micelles or reverse micelles.
8. Biological methods: Biomolecules or living cells being used as synthetic reactors.
9. Thermolysis (e.g., pyrolysis, spray pyrolysis) strategies: Reactions in flames and thermal decomposition.
10. Arrested precipitation (mainly for semiconductors and oxides): Desired material is precipitated from an organometallic precursor solution.
11. Hybrid methods: More than one of the methods described above is used in a systematic combination to produce complex structures.
12. Solvated metal atom dispersion (SMAD): Nanoparticles are synthesized from metal vapors deposited in solid matrices of solvents, which upon heating evaporates to create the nanostructure. Synthesis of protected clusters is also possible if a capping agent is present in the solvent used.

Since NPs are made up of atoms, a two-phase colloidal system can be categorized in terms of the dispersed phase and the dispersion medium. The dispersed phase and the dispersion medium can be gas, liquid, or solid, except for the combination *gas in gas*. Therefore, NPs dispersed in an amorphous solid is a colloidal

system and consequently a *nanofluid*. A dispersion of nanomaterials in a fluid medium is generally referred to as *nanofluid*. Here, the fluid is a liquid at ordinary conditions of temperature and pressure, and hence supercritical fluids and gases as the dispersion phase can be omitted. However, it is worth mentioning that the synthesis of NPs in media such as solid matrices [9.82] and supercritical fluids [9.83] is a highly advanced research area. From the historical perspective discussed above, it is also important to remember that some of the early applications of NPs were in the form of particles embedded in glasses. Supercritical fluids are attracting a great deal of interest currently. Generally these fluids are mostly termed as colloids. The nanomaterials so prepared can be in the form of a fluid or solid. In many cases, applications of these materials will be in the form of solutions or dispersions, called nanofluids. They may also be used as powders, often referred to as nanomaterials. Particle films, pastes, emulsions, and many other forms may also be used.

9.2.2 General Issues of Concern

For devising a synthetic strategy, several factors of interest should be taken into account.

Thermal Stability

NPs being metastable systems will transform to stable materials having global energy minima in the free energy landscape. Thus, they will transform back to the bulk form at infinite time. Mostly, the time involved has no practical consequence. For example, Faraday's colloids, made in 1856 (and reported in 1857), are still stable [9.6]. In other words, even though the bulk metal is more stable, the comparison is similar to that comparing the stability of graphite in comparison with diamond. Although diamond is metastable, it will not become graphite at normal conditions of temperature and pressure even in a millennium. Diamond-to-graphite transformation kinetics is very slow and hence insignificant under normal conditions. The situation of NPs in suitable media is analogous and is referred to as *kinetic stability*.

Dispersibility in Diverse Media

An NP usually has two entities: a core, which can be ceramic, metallic, or polymeric, and a thin shell, which also can be ionic, molecular, polymeric, ceramic, or metallic (Fig. 9.2). For this review, the core is always a noble metal which governs the properties of the NPs. The shell which is usually used to provide a protective

Fig. 9.2 Schematic of an NP with metallic core and organic shell. The shell may also be an extended solid such as SiO₂

layer is important in a number of applications such as those utilizing the luminescence of the particles. Moreover, the chemical nature of the shell determines the dispersibility of a NP.

Generally, the molecular shell will have a characteristic chemical affinity to the core due to its specific atoms or groups. In the case of a metal NP such as gold, for example, the metal can bind with a sulfur atom of the thiolate ($-SR$) group, a common protecting ligand, to form a protective shell. Such a bond present on the surface of the NP is termed a protective monolayer or capping layer, and the NP is called a protected or capped NP. The chemical link so formed renders thermal stability to the system. The weaker the bond, the more easily it desorbs from the surface of the NP and hence the NP will be less stable. Therefore, the binding between metal and the active head group binding on the ligand is an important parameter influencing the thermal stability of the nanosystem.

It must be emphasized that the shell need not be a molecule. In specific examples, the shell will be an inherent part of the core, like in the case of silica NPs. Here, the surface will have a layer of hydroxyl groups and hence the particles can be easily suspended in water. A hydrocarbon monolayer in contrast can disperse the particle in organic solvents. In a similar manner, Au NPs can be made hydrophilic or hydrophobic. For reactive NPs such as copper, the surface is susceptible to oxidation and when the particles are exposed to air, a layer of oxide will form over the surface.

Depending upon the medium, the tail group can change its nature especially for end groups such as $-COOH$, $-NH_2$, $-OH$, etc. These groups will change form depending on the pH of the medium. In acidic media, the $COOH$ group, for example (in the case

of a —COOH -terminated monolayer), will not become ionized and will remain as —COOH , whereas in alkaline media it will become transformed into —COO— by losing H^+ . These surface charge modifications play an important role in applications such as drug delivery. Sometimes, the pH changes can affect the core as well.

Nanoparticles prepared by diverse routes and covered by a variety of activators and dispersants [9.84] such as laurate salts ($\text{CH}_3(\text{CH}_2)_{10}\text{COO—X}$), oleic acid ($\text{CH}_3(\text{CH}_2)_7\text{CH=CH}(\text{CH}_2)_7\text{COOH}$), etc., and dispersed in different media such as transformer oil, water, ethylene glycol, etc., were used for early conductivity studies [9.85]. Generally, surface functionalization is done so that the NP surface is friendly to the medium in which NPs are dispersed. The core-shell structure of an NP system is not limited to spherical particles. The very same general structure may be considered for anisotropic structures such as NRs, nanotubes, nanoshells, etc., where a chemically compatible shell is put around the nanosystem to make it go into the solution, biological environment, etc.

Chemical Compatibility and Ease of Surface Manipulation

When NPs of the same core size are considered for several applications, the above parameters attain significance. The synthetic conditions determine the size, shape, and properties of NPs as to be expected from a method producing metastable systems. Kinetically, an NP is always trapped in a local minimum of free energy, and the synthetic parameters are crucial in deciding the final product. Hence, to get uniformly the desired core size, it is essential to follow the same experimental conditions. Usually, this poses limitations in the adaptability of the system to various chemicals and conditions.

Post-synthetically, solvent compatibility can be modulated by changing the monolayer on the NPs. This process is often termed the ligand exchange, in which one monolayer of ligand molecules present on the NP surface are exchanged with another one in the medium. This exchange process usually results in equilibrium between the molecules in the adsorbed and free states. Repetition of this process a few times can complete the exchange process.

Chemical modification of the monolayer is similar to solution chemistry with simple molecules. Utiliz-

ing the chemistry of monolayers, suitable post-synthetic changes are made on NPs. For example, by employing functional group chemistry, a given monolayer can be polymerized or can be included into a polymeric matrix. This can be achieved via chemical, thermal, and photochemical processes. In specific cases, post-synthetic modification can result in the entrapment of nanosystems inside the cavity of a large molecule so that the nanosystem can be transferred into a suitable medium. The use of dendrimers and cyclodextrins are examples of this kind of chemistry.

Size Control and Monodispersity

An ideal synthetic strategy should produce particles of a given size distribution through a simple process. A narrow size distribution is always desired. Post-synthetic processes are utilized if a methodology fails to generate particles with a narrow size distribution. This involves selecting particles of interest or converting one system to another. However, post-synthetic methods also have their own advantages and disadvantages.

When a methodology produces of a variety of sizes in the as-synthesized particles, selection of a given size can be done by post-synthetic approaches. Several such processes exist. The first is size exclusion chromatography. Here, the mixture of NPs is passed through a size-selective stationary phase (e.g., a gel) having definite pore sizes. The applied eluent (solvent) elutes the material as a function of size. Agarose and Sephadex are the two common media used. The next method involves solvent-selective precipitation. In this method, by progressively changing the polarity of the medium from low to high, larger particles are forced to precipitate from the mixture. One disadvantage is that the stability of the material in different solvents may vary. However, by repeating this process, precise control over the size of the resulting NP is possible. Digestive ripening is also used to obtain monodisperse samples. In this method, the NP is digested with the protecting agent used during the synthesis at elevated temperatures. Smaller sized particles become consumed during the ripening process. Ostwald ripening or particle coarsening is a similar process where the as-prepared particles are allowed to age for a finite period during which large particles grow at the expense of smaller particles, narrowing the particle size distribution. This may be achieved along with temperature cycling.

9.3 Common Synthetic Routes for the Preparation of Noble Metal NPs

This section outlines the various strategies applied for synthesis of noble metal NPs. The discussion will mostly pertain to conventional spherical NPs. Synthesis of other shapes are extensions of some of these methods and a brief description of some of these will also be provided without going into the details.

9.3.1 Solution Phase Routes by Chemical Reduction

Metal atoms produced by the reduction of metal ions can upon aggregation produce NPs. The growth of these aggregates can be arrested at a desired stage by the use of protecting agents. A general reduction reaction can be represented as

Instead of supplying the electron directly, the oxidation of the reducing agent results in the production of electrons bringing about the reductions.

where the reducing species (reducing agent) having a finite charge loses some specific amount of charge and becomes oxidized. It is important to mention that both the metal and the reductant may not contain any distinct charge and those mentioned are only nominal. The net reaction

and its feasibility depends on the thermodynamics of the process, which in turn is governed by the electrochemical potentials of the corresponding half-cell reactions (standard reduction potentials). The sum of the reduction potentials (with their signs) of reactions (9.1) and (9.2) gives a net positive value, thus the process is thermodynamically feasible. This implies a net negative free energy change of $\Delta G = -nFE$, where ΔG is the free energy change of the reaction (9.3), n is the number of electrons involved, F is the Faraday constant, and E is the electrochemical potential of the reaction (9.3). Since the potential must be taken at the appropriate conditions, E must be considered not E° . Thermodynamically feasible reactions have negative ΔG .

When the ions present in the solution are in complex form, the reduction potentials are not the only criteria that determine the feasibility of reduction. Ions present in complex form will have different potential compared to bare ions. For example, simple Au^{3+} (as in $[AuCl_4]^-$) can be reduced using mild reducing agents

such as carboxylates or alcohols. However, in the presence of excess thiol this is not possible. The formation of metal thiolates makes the reduction of these complexes and reduction will only take place with strong reducing agents such as borohydride. In the presence of gold metal particles, reduction with mild reducing agents is possible, since the reduction occurs on the surface of gold. The reduction of gold ions by ascorbic acid in the presence of gold seeds during the preparation of GNRs (discussed below) is an example.

A molecule or ion itself can act both as the reducing agent and as the capping agent as in the case of citrate, amines, alcohols, thiols, etc. Reduction and the subsequent stabilization action of trisodium citrate for making Au NPs is the best example. In the recent past, several such examples have been reported where a variety of amines, alcohols, thiols, complex ions, etc., were used. Since alcohols are not good protecting agents, polyols containing a larger number of hydroxyl groups per molecule are used, which effectively chelate (multiply coordinate) the metal ions. A summary of the specific reduction processes employed is presented in Table 9.1.

Strong Reducing Agents

Reduction of metals with a large negative reduction potential is very difficult and demands careful control of the reaction conditions. The use of a strong reducing agent can minimize the solvent and other reactants present. For example, the presence of water should be avoided if the reagent is very strong to avoid the following reaction

The standard reduction potential of this reaction is -0.828 V. Solvated electrons are the most powerful reducing agents. They can be prepared in the laboratory by dissolving alkali metals in aprotic solvents like diethylether or tetrahydrofuran in the presence of excess complexing agents such as crown ether. The reaction can be depicted as

However, in the presence of smaller amounts of complexing agent, an alkali (the alkali metal anion) will be formed [9.86],

Since the thermal stability of the above reagents is less, the reactions should be done at lower tempera-

Table 9.1 Summary of various solution-phase reduction processes employed to make metal NPs

Method	Metal/reducing agent	Example	References
1. NaBH ₄ route	Metal ion/BH ₄ [−]	Au, Ag	[9.88, 89]
2. Amine route	Metal ion/APS ^a , AES ^b	Ag	[9.90]
3. Polyol route	Metal ion/ethylene glycol	Ag, Pd	[9.91]
4. Citrate route	Metal ion/Cit ^{3−}	Au, Ag	[9.6, 92]
5. Polyvinylpyrrolidone route	Metal ion/PVP ^c	Pd	[9.93]

^a APS: 3-aminopropyltrimethoxysilane
^b AES: 3-(2-aminoethylaminopropyl)trimethoxysilane
^c PVP: polyvinylpyrrolidone

tures. This approach has been successfully employed for the synthesis of several nanocrystalline metals and alloys [9.87].

Trialkylborohydrides (ABEt₃H, A = Li, Na, K) are another class of strong reducing agents. Some methods utilizing aralkyl aluminum as the reducing agent have also been reported. A variety of transition metal NPs have been synthesized through the use of strong reducing agents [9.87, 94].

9.3.2 The Most Common Methods for Gold NPs

Two of the most common methods used for the synthesis of GNPs, namely the citrate route and the Brust method, are described in detail in this section. Other common methods for the preparation of metallic NPs are also briefly discussed.

The Citrate Route

This method also known as the Turkevich method [9.95], is the most used and easy-to-use method for the synthesis of colloidal gold NPs having a mean diameter

of ≈ 15 nm. In this approach, the reducing agent used, sodium citrate (other reducing agents, such as amino acids, have also been employed successfully), also acts as the stabilizing agent, reducing Au³⁺ ions to atoms and subsequent aggregation results in the formations of NPs at elevated temperature. The NPs produced via this method are mostly monodisperse and spherical with a diameter of around 10–20 nm. The reduction in the amount of sodium citrate can increase the size of the resulting NPs. In 1973 Frens modified this method to obtain Au NPs of predetermined size by varying the trisodium citrate to gold ratio [9.96]. Transmission electron microscopy (TEM) images of the particles obtained by this method are shown in Fig. 9.3.

Covering citrate-protected particles with various molecules or ceramics such as silica, can enable the NPs to be taken out of the solution, and redispersed. Since these particles can be good starting points for various investigations in biology and materials science, this approach is widely practiced [9.97].

Brust–Schiffrin Reduction

The Brust–Schiffrin method [9.98] involves phase transfer of [AuCl₄][−] from the aqueous phase to the organic phase by a phase-transfer reagent, tetraoctyl ammonium bromide, and subsequent reduction of it at the interface by NaBH₄ in the presence of a thiol, resulting in the production of thiolate (RS[−])-protected GNPs having a very small core diameter (range 1–5 nm). Variation of the Au/thiol ratio used in the synthesis can bring about a change in core dimension. A smaller Au/thiol ratio (a higher thiol concentration) produces smaller particles. The main advantage of the process is that the synthesized Au NPs can be repeatedly isolated and redispersed in organic solvents without aggregation or decomposition. The NPs can be taken out of the medium and dried, and the powder can be stored for a long time and can again be redispersed. Figure 9.4

Fig. 9.3a,b TEM images of Au@citrate prepared by the citrate reduction method with average particle diameter of 15 nm. (a) low magnification and (b) higher magnification, lattice resolved image

Fig. 9.4a,b Typical TEM images of Au@ODT NPs, prepared by the Brust method. Particles of 3 nm diameter are observed. (a) low magnification and (b) lattice resolved image showing single crystalline nature of most of the particles (courtesy T. Pradeep)

shows the representative image of NPs obtained in such a synthesis with a 1 : 2 Au : S ratio.

Another main advantage of this approach is that functionalization of the particles formed is feasible by using functionalized thiols during the synthesis. Alternately functionalization can be realized via exchange reaction (described earlier), where one kind of thiol or another ligand is exchanged with that on the NP surface. These NPs, often referred to as monolayer-protected clusters (MPCs), have been extensively reviewed [9.99, 100]. Several ways exist to conduct the synthesis. Using acid [9.101] for phase transfer helps to avoid phase-transfer catalyst impurity in the ensemble. The high degree of monodispersity can induce two-dimensionally ordered lattices on a TEM grid. Digestive ripening (discussed earlier) [9.102] has been employed to reduce the particle size distribution in the Brust method. After this, the resulting particles with a narrow size distribution arrange to give 2-D and 3-D superstructures [9.103].

Similar superstructures can be produced with silver as well. Here, a variety of reducing agents can be used instead of NaBH₄ and the synthesis can be achieved without phase transfer. Several reports exist on the preparation of water-soluble NPs, synthesized using water-soluble thiols such as glutathione [9.104] and mercaptosuccinic acid (MSA) [9.105]. Reduction of the Au–thiolate complex in methanol by NaBH₄ in water is the important step during the reaction. The NP being insoluble in methanol precipitates out. This is washed repeatedly using methanol and is redispersed in water. Clusters formed using MSA are known to form well-arranged superlattices (SLs) [9.106]. Glutathione is known to produce a variety of molecular clusters starting from Au₈ to Au₃₉, which can be size separated using polyacrylamide gel electrophoresis (PAGE) [9.107].

Electrochemical Reduction

Chemical reduction is the most extensively investigated and employed method for making nanomaterials. However, various other methods have also been employed for the synthesis of special nanosystems. Electrochemical reduction where the metal is dissolved at the anode and the metal ion formed is reduced at the cathode is one of the prominent ones. To avoid the deposition of the resulting NP on the cathode (leading to electroplating), the process is done in the presence of a stabilizer. Nanoparticles of palladium (Pd) of 4.8 nm diameter have been synthesized by this approach by passing 0.1 mA cm² current at 1 V in a 0.1 M tetraoctylammonium bromide (TOAB) solution in 4 : 1 acetonitrile : tetrahydrofuran (THF) mixture [9.108]. The resultant NPs, which precipitated out could be re-dispersed in THF or toluene. A similar methodology can be used for other metals such as silver [9.109] and also for the preparation of GNRs [9.110].

Radiolytic Reduction

Reduction under various radiations such as visible, ultraviolet (UV), x-rays, and γ -rays is another method for synthesizing NPs. Metal salts solutions are irradiated in presence of stabilizing agents. In photoreduction with gamma rays, various species are generated in the medium, depending on the photon energy absorbed. In an aqueous solution, H₂, H[•], H₂O₂, OH[•], and e[−] are produced by radiolysis of water. Nitrous oxide in the medium scavenges the electrons generated, which further generates OH[−] and OH[•] [9.111].

Alcohols react with the formed radical according to the following reaction

The $\text{CH}_2\text{OH}^\bullet$ radical in the reaction mixture acts as the reducing agent according to the equation

The reduced metal and formaldehyde are the final products of the reaction and if the solvated electron itself can be used, the reduction is more powerful. Nanoparticles of Au [9.112], Ag [9.113], Cu [9.114], and Co [9.115] have been synthesized using this methodology. This approach is especially useful for the preparation of complex structures such as core–shell particles, where a metal core is coated with a shell of another metal. A few examples are Au@Ag [9.116], Au@Pt [9.117],

Pt@Au [9.117], Au@Pb [9.118], etc. Radiolysis is done on a mixture of a metal NP and aqueous metal ion using a ^{60}Co source. The surface of metal NPs become charged due to the transfer of electrons from the generated radicals. These NPs thus reduce the metal ions which are deposited on the surface of the NPs, resulting in core-shell geometry. Using a similar strategy, the size of Au NPs (repeated radiolysis) were modulated [9.119].

Thermal Decomposition of Organometallics

Decomposition of corresponding metal carbonyls by heating in an inert solvent at elevated temperature in the presence of a suitable stabilizing agent is another way to produce metal NPs. For example, heating $\text{Co}_2(\text{CO})_8$ in decalin at 130–170 °C can produce Co NPs [9.120]. Usually, nitrogen-containing polymers are used as stabilizers in the reaction. It is known that the stabilizer will form metal cluster macromolecules, where these polymers act as a complexing agent. The particle size can be controlled by varying the functionality of the polymer. Various NPs made up of Fe [9.121], Ni, Cr, Mo, and W [9.122, 123], as well as alloy NPs have been prepared by employing different polymers. It is to be noted that the ligands should be selected with care as they should be stable at high temperatures. A new metastable Co phase ($\epsilon\text{-Co}$) obtained through the use of this method has also been reported [9.124]. The stabilizer used in the reaction was trioctylphosphine oxide (TOPO), and in the absence of TOPO this phase was not formed. The formations of various kinetically stabilized shapes have been studied in detail [9.125, 126]. Mixtures of carbonyls and other organometallic reagents were used to prepare FePt [9.127] and CoPt [9.128] alloy and core-shell NPs. Thermal decomposition of metallocenes is also known to form NPs [9.129, 130]. Various ligands such as 1,5-cyclooctadiene (COD), 1,3,5-cyclooctatriene (COT), dibenzylidene, and cyclooctenyl ($\text{C}_8\text{H}_{13}-$) have been used in various syntheses. Some examples of NPs synthesized through the use of this approach include Co, Ni, Ru, Pd, and Pt NPs, Co and Ni NRs, and CoPt, CoRu, CoRh, and RuPt nanoalloys.

Microwave-Assisted Synthesis

A microwave-assisted approach has been abundantly employed for the synthesis of a variety of organic and inorganic materials. This method can be utilized for both synthesis and processing aspects [9.131]. This method is less time-consuming and heating is achieved from within. Usually the mixture to be irradiated is placed inside a domestic microwave oven working at

a frequency of 2450 MHz and the mixture is stirred. In the case of metals, the metal ion and the reducing agent in a suitable solvent are placed in the oven and especially in the case of Au and Ag, this approach is known to form highly monodisperse NP samples (when compared to thermal reduction) [9.132]. Polyols are one of the most effective reductants for metal ions using microwave irradiation and the process is often referred to as the microwave polyol process [9.133]. Microwave irradiation of a mixture of poly(vinylpyrrolidone) (PVP), ethylene glycol, NaOH, and H_2PtCl_6 in water resulted in the formation of 2–4 nm Pt NPs [9.134]. A similar strategy was employed for the synthesis of 6 nm diameter Ni NPs as well [9.135]. This synthesis methodology can be automated by adapting it to continuous-flow reactors [9.136]. An excellent review on microwave-based methods for NP fabrications is available in the literature [9.137].

Sonolysis

Ultrasound (typically at 20 kHz) irradiation of the reaction mixture is utilized for the synthesis of NPs in this methodology. Here NP formation here is termed cavitation, which involves the implosion of cavities of very small dimensions on nanosecond timescales. This leads to the formation of local hot spots of very high temperature in the range of 5000 K. The reactant (a precursor species like organometallics) becomes trapped in this and is decomposed at this temperature. The products are instantaneously quenched by the surrounding solvent medium, resulting in the formation of amorphous NPs. A variety of transition metal NPs has been synthesized using this strategy [9.138]. Sonolysis of $\text{Fe}(\text{CO})_5$ in decane in the presence of oleic acid resulted in the formation of 8 nm oleic acid protected Fe NPs [9.136]. Alloy NPs can be also prepared by this method. This approach has also been reviewed in [9.139].

9.3.3 Specialized Synthetic Strategies – Anisotropic NPs

As discussed earlier, specialized strategies are needed to synthesize nanosystems of various shapes with control over size and shape. Most of these are either an adaptation or modification of the methods described above. However, specific molecular interactions or templates can be used to facilitate shape-selective synthesis. It has been found that metal ions can be reduced via radiolytic [9.140] and photochemical [9.141, 142] methods. NPs of various morphologies such as rods, triangles, hexagons, etc., can be generated using the photochem-

ical method [9.141, 142]. Template-assisted [9.143] methods have been used to make 1-D nanostructures with uniform size and controllable physical dimensions. The galvanic displacement reaction [9.144] is another method to make GNPs and their hybrid forms. This method has been widely used to produce nanostructures with different morphologies, including plates, cubic nanoboxes, cubic nanocages, nanorings, nanoboxes, single-walled nanotubes, and multi-walled nanoshells or nanotubes [9.145, 146]. Many other techniques such as sonolysis [9.147], microwave-assisted synthesis [9.148, 149], the hydrothermal method [9.150], etc., are being used to make gold and silver NPs. All the above-mentioned methods come under the category of bottom-up approaches for synthesizing NPs. The following section describes some of the important strategies employed in this regard. Only brief descriptions are given.

Seed-Mediated Growth Method

This is one of the most widely used strategies for the synthesis of anisotropic NPs of gold and silver. It is a modified version of Zsigmondy's *nuclear* method [9.151], which involves two steps. However, the seed-mediated method usually produces larger NPs of size 30–100 nm. This was first demonstrated by Brown and Nathan [9.152]. The first step involves the synthesis of *seed NPs* by reduction of metal salts in the presence of stabilizing agents. Usually this is carried out by using a strong reducing agent such as sodium borohydride (NaBH_4). It must be noted that the seed need not always be a metal NP. Subsequently in the second step growth of seed NPs into the desired shape happens in a growth solution containing excess metal ions, a surfactant or shaping agent, and a mild reducing agent. Here, the reduction of metal salts is facilitated on the surface of the seed NPs, and due to the presence of the surfactant molecules which form suitable templates, the growth happens to yield NPs of the desired morphology.

Murphy et al. devised various strategies based on the seed-mediated growth approach to make NPs of various shapes [9.153, 154]. Noble metal NPs of diverse structures such as rods [9.155], wires [9.156], triangles [9.157], stars [9.158], flowers [9.159, 160], etc., can be synthesized using this method. Tuning of size is possible by varying the amount of seed NPs added to the growth solution. This strategy has been successfully used for the synthesis of GNRs. The presence of external agents such as molecules or ions can influence the growth direction and can result in the formation

of a different morphology. For example, the presence of iodide ion in the growth solution during the synthesis of GNRs, results in the formation of triangular nanoprisms [9.161]. Iodide ions adsorb on gold seeds to suppress the growth along the Au(111) direction, leading to the formation of Au(111)-faced triangular nanoprisms. Even the counter-ion present on the surfactant used can influence the morphology. When the counter-anions on cetyltrimethylammonium bromide (CTAB) were replaced with chloride ions (instead of the original bromide), a rice-shaped NP formed instead of rods. The concentration of surfactant molecules is another parameter that affects the shape, since the shape of the micelles formed by the surfactant during the growth changes with the concentration. A method developed by Mirkin et al. [9.48] is an excellent example for this concentration dependence; they synthesized nanoprisms by changing the parameters in seed mediated synthesis. This involves a three-step growth process where gold seed NPs of ≈ 5 nm were added into the growth solution containing the capping agent CTAB, gold ions, a reducing agent (ascorbic acid), and NaOH, resulting in the formation of gold nanoprisms in very good yield. Synthesis required a saturated CTAB solution for good yield with uniform morphology.

Seedless Synthesis:

Modification of Seed-Mediated Synthesis

Seedless synthesis is a slight modification of the above-mentioned method. In the above method, the purity of the seeds determines the quality of the resulting structures. Hence, Pradeep et al. [9.162] and Jana [9.163] separately showed that gold nanostructures can also be formed without the presence of the seeds. Jana illustrated that, without the use of seeds, near-monodisperse gold and silver NRs, spheroids, NWs, platelets, or cubes of 4–50 nm dimension and controllable aspect ratio (AR), can be prepared by introducing a mixture of strong and weak reducing agents into the micellar solution of a metal salt. Here, the strong reducing agent initiates nucleation and the weak reducing agent induces the NP growth [9.163]. This strategy was found to be extendable to semiconductors as well. Pradeep et al. studied the role of sodium borohydride (NaBH_4) in the formation of GNRs [9.162]. They found that addition of a calculated amount of NaBH_4 directly into the growth solution leads to the formation of uniform GNRs. They also studied the formation of GNRs with various seeds of metals of widely differing crystal structures, and understood that there is no variation in the properties of the GNRs formed. The role of NaBH_4 in the growth of

Fig. 9.5 (a) Scanning electron microscopy (SEM) image of octahedral gold nanocrystals. The imaged regions show extensive self-assembled structures. (b) UV/Vis absorption spectra of octahedral NPs of different sizes. Maximum absorbance of the spectra has been normalized (after [9.150])

GNRs, which was not well understood in earlier reports, was investigated in detail. They found that there is a relation between the longitudinal plasmon peak and the concentration of NaBH_4 . To validate this further, the observed dependence was compared with the dependence of the residual concentration of NaBH_4 in the seed solution left over from the growth solution after the GNR growth. It was suggested that the addition of NaBH_4 leads to in situ formation of the seed particles, which enables the growth of GNRs.

Biological Synthesis

As an alternative to the use of chemicals, biological synthesis was advertised as a safe and ecofriendly approach for synthesis of GNPs. Here, the NPs are synthesized using organisms ranging from bacteria to fungi, various parts of plants, biological extracts, etc. One important advantage of this method is that it yields NPs capped with biological entities, which consequently have improved biocompatibility so that they can be used in many biomedical applications. Noble metal NPs of various shapes such as triangles, wires, spheres, plates, etc., have been synthesized via this method. A classical example is the high yield synthesis of thin, flat, single-crystalline gold nanotriangles (NTs) by the reduction of aqueous chloroaurate ions ($[\text{AuCl}_4]^-$) using an extract of the lemongrass plant (*Cymbopogon flexuosus*) [9.164]. The reducing agent in the reaction was found to be *aldoses* (reducing sugars) present in the lemongrass extract. Similar examples of Au NP preparation using extracts of tamarind leaf [9.165], *Cinnamomum zeylanicum* leaf [9.166], the unicellular green algae *Chlorella vulgaris* [9.167], *Rhodospseudomonas capsulata*, are available in the literature.

Hydro/Solvothermal Synthesis

This method involves the synthesis of NPs in a solvent at elevated temperatures under high pressure in an

autoclave. The solvent (in most cases water) acts both as a catalyst and occasionally as a component of solid phases. Since several other solvents, including water, can be used for the synthesis this approach is generally termed solvothermal synthesis [9.168]. In hydrothermal processes, initial properties of water can be modified by introducing additives. This is a versatile strategy where various solvent systems such as polar solvents (e.g., aqueous solutions containing HF, or other acids or bases to modulate pH) or nonpolar solvents (e.g., pure, supercritical) are used for the dissolution–recrystallization process. Various nanostructures have been synthesized using this approach. The hydrothermal reaction of an aqueous solution of HAuCl_4 , trisodium citrate and CTAB has been reported to produce octahedral gold nanocrystals (Fig. 9.5a) [9.150]. Gold octahedra with varying average sizes were synthesized by heating the different reactants at 110°C for different time periods. Evidence of the formation of differently sized octahedra was seen in the absorption spectra where the surface plasmon resonance (SPR) band shifted from 543 to 635 nm (Fig. 9.5b). Structurally, the octahedra are bounded by specifically bound by (111) facets [9.150]. Technologically important nanostructures composed of Pd–Cd having high hydrogen storage capacity were also synthesized by this method. Here, various nanostructures with varying concentrations of Cd were grown directly on a solid substrate [9.169]. Because the method is low cost and environmentally friendly where substrates are at comparatively lower temperatures it is advantageous for the creation of diverse nanostructures on temperature-sensitive substrates.

Galvanic Replacement Reactions

This method (also called electroless plating) was introduced by Brenner and Riddell [9.170]. In this method the spontaneous reduction of metal ions to metallic particles and films occurs at equilibrium in the absence

of an external electric field. Due to its ease of operation, this method has attracted wide attention. It is highly versatile and can be used to make a wide range of metal/substrate combinations, including metal-on-metal, metal-on-semiconductor, and metal-on-insulator types. This is particularly important in the area of electronics with regard to metal deposition on a circuit board, for example. The process, *electroless deposition* includes three fundamentally different mechanisms such as autocatalytic, substrate catalyzed, and galvanic displacement (immersion) processes in which the galvanic displacement reaction proceeds in an entirely different manner and the deposition is carried out in the absence of an external reducing agent.

Galvanic replacement reactions are single-step reactions that work depending on the differences in the standard electrode potentials of various elements, leading to deposition of the more noble element and dissolution of the less noble component. The electrons for the reduction are derived from the valence-band electrons of the substrate (Fig. 9.6a). Until the permeation of oxidized substrate ion into the solution through the metals film stops, the reaction will continue. The formation of a dielectric layer of oxidized substrate that hinders the electron transfer can also arrest the reaction. There are several advantages with this approach. For example, most synthetic processes use surfactants to obtain anisotropic nanostructures with smooth surfaces. However, attachment of surfactant molecules on the surface is not desirable for many applications. The presence of surfactants usually increases the electrical resistance, hence limits the use of these NPs as conductive components in electronics. Electroless deposition avoids the use of surfactant molecules whereby the NPs can be directly utilized without loss of electrical properties.

Preparation of pristine Ag nanoplates on semiconducting GaAs wafers (Fig. 9.6b) has been reported [9.171] through a galvanic reaction between an aqueous solution of AgNO_3 and GaAs (9.11). A droplet of aqueous solution of AgNO_3 was added on a GaAs wafer (treated with aqueous hydrofluoric acid solution) to grow silver micro/nanostructures via the galvanic reaction

Controlling the concentration of AgNO_3 resulted in the tuning of the morphological parameters of the Ag nanoplates. At high concentration of AgNO_3 , thicker Ag nanoplates were obtained. Electrons for the re-

duction are provided by the germanium–germanium bonds leading to the formation of Ag(s) from Ag^+ and Ga(s) becomes oxidized during the process via a redox reaction.

An unusual variety of Ag nanostructures called nanoinukshuks (Fig. 9.6c), was synthesized by immersing n-type Ge(100) in aqueous AgNO_3 solution [9.172]. When the Ag^+ ion concentration reached 1 mM, nanoinukshuks were obtained at room temperature on flat or rough, oxidized germanium surfaces. The nanoinukshuks were composed of 300 nm-diameter stacked hexagons, which can grow perpendicular to the (111) planes of the silver hexagons. Synthesis was carried out with different Ag salts, such as AgClO_4 and $\text{Ag}(\text{CH}_3\text{CO}_2)$. With AgSO_4 , flat dendritic structures formed. A close-up view of the tip of the nanoinukshuks is given in Fig. 9.6c. Gold dendritic nanostructures can also be synthesized using HAuCl_4 , H_2O , and zinc through this methodology. Dendritic structures formed by immersing a Zn plate in a container with HAuCl_4 solution at room temperature and ambient pressure (Fig. 9.6e) [9.173].

The same strategy can be employed for preparing Ag dendritic nanostructures as well (Fig. 9.6d) [9.174].

Hollow metal nanostructures can also be produced in this way. The structure can be made hollow or have porous walls. This change can be brought about by using a less active metal salt precursor. A wide variety of gold-based hollow nanostructures of different morphologies, including cubic nanoboxes, cubic nanocages, nanorings, nanoboxes, single-walled nanotubes, and multi-walled nanoshells or nanotubes [9.175–177] have been synthesized using this strategy. More details of these reactions is given in the discussion of the reactivity of these anisotropic systems in Sect. 9.5.1.

Photochemical Synthesis

As described in previously, the reduction of metal salt precursors can also be carried out by radiolytic and photochemical methods. Here, there is no external reducing agent involved and radiation becomes absorbed regardless of the light-absorbing solutes and products. Also, the number of reducing equivalents generated by radiation being known exactly, the rate of the reduction reaction can be accurately determined. This methodology does not require any specific and expensive instrument. All this makes this approach highly attractive for synthesis on metallic nanostructures.

Rod-shaped NPs were the first anisotropic NPs to be synthesized by reduction of metal salt by UV irradiation [9.178]. Here, a rod-like micelle formed by hexadecyltrimethylammonium chloride becomes embedded by AuCl_4^- , and the reduction of these ions to Au^0 is achieved through photochemical irradiation ($\lambda_{\text{max}} = 253.7 \text{ nm}$). However, synthesizing uniform, AR-controlled rods is difficult because an increase in length of NRs will always result in an increase in spherical NP impurities. Yang et al. [9.179] reported an improved methodology which produces NRs with well-controlled AR. This method was similar to the electrochemical method described earlier and the reaction mixture had the surfactant CTAB and tetradodecylammonium bromide and the precursor $\text{HAuCl}_4 \cdot 3\text{H}_2\text{O}$. The reduction was achieved by photoirradiation for 30 h ($\lambda_{\text{max}} = 254 \text{ nm}$, $I = 420 \mu\text{W}/\text{cm}^2$). During the process, acetone and cyclohexane were used for loosening the micellar structure. However, additionally, silver nitrate was used in this process to control the AR of the NRs. Also, an increase in the silver ion concentration led to a decrease in the AR of the NRs and when the silver ion was absent a large number of spherical particles formed.

Photo-induced methods have found useful the preparation of large quantities of silver nanoprisms in high yield in the form of a colloidal suspension as well [9.180]. The as-synthesized colloids had distinctive optical properties that directly relate to the shape. The first step of the reaction includes the synthesis of spherical silver particles from an aqueous solution of AgNO_3 using NaBH_4 in the presence of trisodium citrate. A stabilizing agent, bis(*p*-sulfonatophenyl) phenylphosphine dihydrate dipotassium (BSPP) was introduced dropwise into the reaction mixture. The mixture was irradiated with a conventional fluorescent light. The edge length of the nanoprisms in this process was found to be tunable to 30–120 nm range [9.181]. Using dual beam illumination of the NPs, the growth can be controlled, and the process is believed to be driven by surface plasmon excitations. Depending on the wavelength of the illumination, the plasmon excitations lead to the fusion of nanoprisms. The bimodal growth process observed occurs through an edge-selective particle fusion mechanism, with four type 1 nanoprisms coming together in stepwise manner to form a type 2 nanoprism (Fig. 9.7). GNPs of various morphologies such as triangular or hexagonal shapes can be generated using the photoreduction method by mixing Au^{3+} with sodium oxalate and a reducing agent, in aqueous solution under illumination by a mercury lamp for more than 10 min. The size of the GNPs varies from 25 to 200 nm, mainly depending on the duration of light illumination and the concentration of sodium oxalate [9.182].

Electrochemical Synthesis

This is a modification of the process described above, developed to create anisotropy in the formed structures. The electrochemical method was first proposed by Reetz and Helbig in 1994 [9.108]. They demonstrated that by adjusting current density, highly size-selective NPs can be synthesized via an electrochemical reduction method. Diverse nanostructures such as cubes, rods, triangles, plates, etc., have been synthesized by this method [9.183]. It has many advantages over other methods since it has a lower processing temperature and low cost, requires modest equipment, and offers good control of size, shape, and morphology. The experimental setup (Fig. 9.8) for the electrolytic process includes a two-electrode setup for 50–250 ml electrolyte solutions in which the sacrificial anode consists of the bulk metal to be transformed into a metal colloid. In a two-electrode setup, GNRs were recently synthesized in high yield [9.184]. In this process, gold and platinum

plates were used as the anode and cathode, respectively. The electrolytic solution had a mixture of a cationic surfactant or stabilizing agent and a cosurfactant, and the electrodes were immersed in it. During electrolysis, bulk gold metal is oxidized at the anode, and the metal cations at the interfacial region of the cathodic surface are reduced, and in the presence of the capping agent, form GNRs. GNRs with various ARs can be synthesized by this method.

Highly monodisperse gold nanocubes can be synthesized by an electrochemical method, using a surfactant solution and acetone [9.185]. Here also a two-electrode setup with gold and platinum plates as the anode and cathode is used. These electrodes are placed vertically face-to-face inside the cell, separated by Teflon spacers in an aqueous solution of CTAB and a much more hydrophobic cationic cosurfactant, tetradecyltrimethylammonium bromide. Acetone was

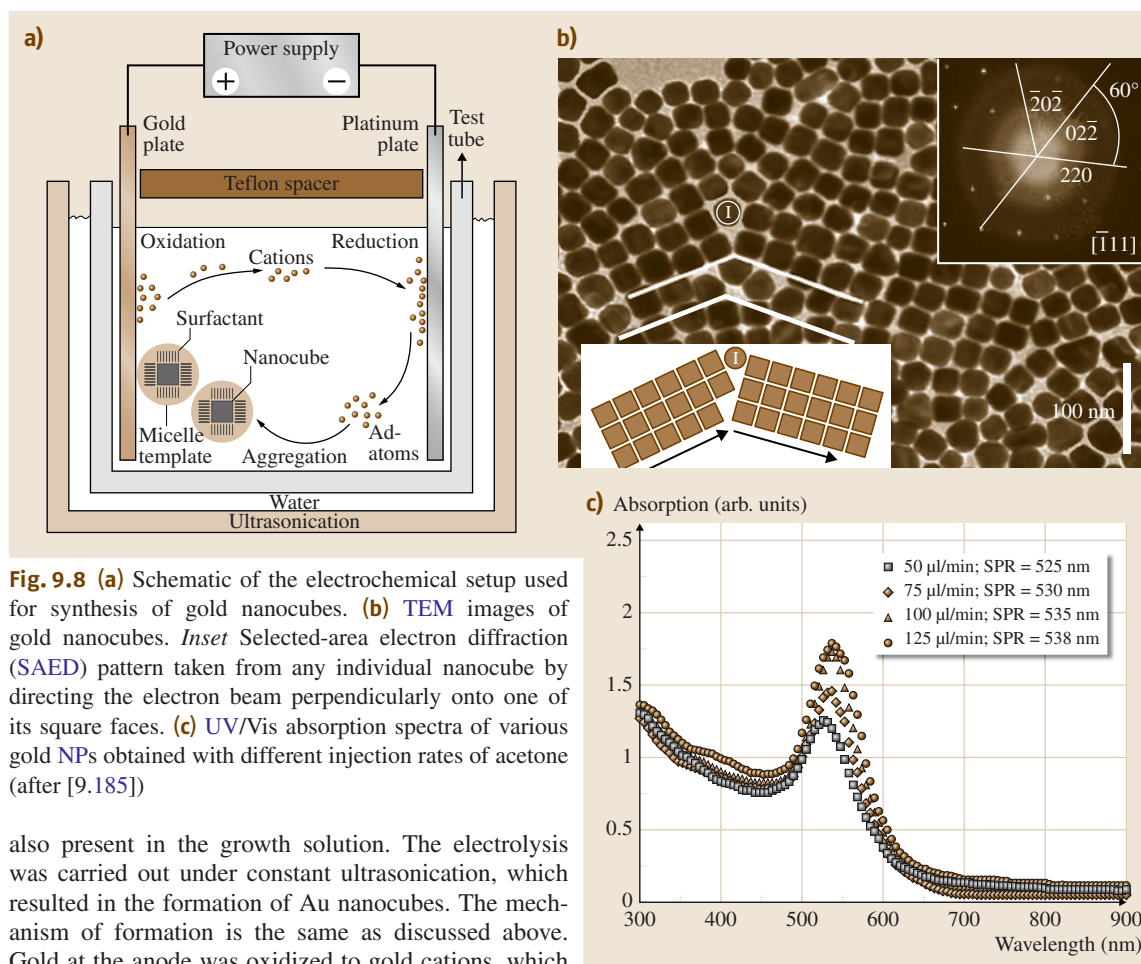

Fig. 9.8 (a) Schematic of the electrochemical setup used for synthesis of gold nanocubes. (b) TEM images of gold nanocubes. (c) UV/Vis absorption spectra of various gold NPs obtained with different injection rates of acetone (after [9.185])

also present in the growth solution. The electrolysis was carried out under constant ultrasonication, which resulted in the formation of Au nanocubes. The mechanism of formation is the same as discussed above. Gold at the anode was oxidized to gold cations, which then migrated to the cathode, where reduction occurred with the formation of gold adatoms (Fig. 9.8a). These adatoms were trapped by the surfactant to form nanocubes (Fig. 9.8b). The surfactant, which doubles as the electrolyte and the stabilizer, also forms a micelle template to control the size and shape of the NPs. The rate of injection of acetone was found to influence the shape of the NP formed. Spherical NPs were formed at lower concentrations of acetone. As the amount of acetone increased a red-shift was observed in the UV/Vis absorption spectra (Fig. 9.8c) of gold nanostructures.

Synthesis of GNRs has also been carried out via an electrochemical method using a simple two-electrode cell [9.186]. In this process, a gold metal plate acts as the anode and a platinum plate as the cathode. A cationic surfactant, CTAB, and a rod-inducing co-surfactant were used as the electrolyte. Using a standard

three-electrode cell with a potentiostat, a platinum foil counter electrode, and a saturated calomel electrode, platinum nanothorns were synthesized electrochemically at room temperature [9.187]. Here, platinum nanothorns (Fig. 9.9) were electrodeposited on glassy carbon substrate in 2 mM K_2PtCl_6 and 0.5 M H_2SO_4 solution by applying a square wave potential between -0.20 and 0.80 V at 10 Hz for 20 min.

Using a templateless, surfactantless, electrochemical method, single-crystalline Ag dendrites were fabricated on a Ni/Cu substrate by [9.188, 189]. The applied potential controlled the morphology and geometry of the Ag particles. The morphology changed from Ag polyhedrons to Ag dendrites, which preferentially grow along the directions in a fractal mode, upon decreasing the potential from -0.4 to -2.0 V [9.190].

Template Mediated Synthesis

Recently, the template-mediated synthesis of 1-D nanostructures with uniform size and controllable physical dimensions has attracted a great deal of interest. The advantages of this method over other methods are: ease of fabrication, adaptability to various compositions of materials, low cost, and high throughput [9.190, 192, 193].

Usually, nanoporous polycarbonate or alumina are used as the template. Metals from which NP is to be synthesized (Au, Ag etc.) are electrochemically deposited in the template structure. First, a small amount of Ag or Cu is sputtered on the template to make a conductive film for electrodeposition. Subsequently, metal is electrochemically deposited onto the conductive template. The template is removed by selective dissolution in the presence of a polymeric stabilizer (e.g., PVP), and the nanostructures are dispersed either in water or an organic medium by means of sonication. Template-mediated synthesis of GNRs is shown in Fig. 9.10. By controlling the pore size of the template, the diameters of synthesized structures can be controlled [9.194]. Similarly, by regulating the amount of metal deposited, the length of the structures can be controlled [9.191].

Other Methods

Gold and silver NPs can also be synthesized via top-down approaches. Nanosphere lithography [9.195] is a powerful tool to produce NP arrays with controlled shape, size, and interparticle spacing. This approach uses self-assembled polystyrene nanospheres

Fig. 9.9 (a) Large area SEM image of platinum nanothorns. TEM images of the platinum nanothorn (b,c) with the corresponding selected area diffraction (SAED) pattern and fast Fourier transform (FFT) in the insets (after [9.187])

as templates. Diverse nanostructures such as disks, chains, triangles, rings, etc., have been fabricated using this method [9.195]. The atomic force microscopy (AFM)-based soft lithographic technique called dip-pen nanolithography [9.196] can produce layers on Au and in combination with wet chemical etching is able to fabricate various nanostructures such as dots, lines, rings, triangles, etc., with nanoscale precision. GNPs have been generated using other top-down strategies such as photolithography, electron beam lithography, etc. [9.197]. However, these processes follow expensive synthetic pathways and are industrially nonscalable. Hence, bottom-up approaches are far more popular for synthesis of NPs.

9.4 Properties of Noble Metal Nanoparticles

Noble metal NPs have received a great deal of attention for many applications due to their extraordinary properties. The spatial confinement of electrons controls the physical and chemical properties of NPs. GNPs are classic systems through which the properties of noble metal NPs can be understood. Properties of GNPs can be varied by altering the size, shape, degree of aggregation, and local environment. They exhibit characteristic colors and unusual optical properties that strongly depend on their size, shape, and the dielectric constant of the surrounding medium. The characteristic wine-red color of spherical GNPs stems from a phenomenon termed localized surface plasmon resonance (LSPR) [9.199, 200]. When electromagnetic radiation of an appropriate wavelength interacts with a metallic nanostructure, the conduction electrons near a metal–dielectric interface will be excited and undergo a collective oscillation relative to the lattice of positive nuclei with the frequency of the incoming light resulting in LSPR (Fig. 9.11). A momentary electric field is generated on the surface of the NP as a result of the oscillations. This can extend into the dielectric over nanometer length scale and hence can give rise to an enhancement of the incident field by several orders of magnitude, resulting in novel properties of NPs. One of the first investigations of the interaction between NPs and light was done by Faraday in the nineteenth century on his gold colloid.

A complete theory to understand plasmon resonance absorption and color of metal colloids in solution was developed by *Gustav Mie* in 1908 when he studied the

theory behind the scattering and absorption of electromagnetic radiation by a sphere [9.201]. In its original form, Mie's theory was able to explain the spectral properties of spherical particles. The theory showed that the total extinction cross-section comprises contributions from the scattering and absorption cross-sections, i. e., the extinction cross-section, $\sigma_{\text{ext}} = \sigma_{\text{abs}} + \sigma_{\text{scat}}$ (absorption cross-section + scattering cross-section). When the size of the NP is smaller than the wavelength of light ($\lambda \gg 2r$, where r is the radius of the NPs), Mie's theory reduces to [9.202–204]

$$\sigma_{\text{ext}}(\omega) = 9 \frac{\omega}{c} \varepsilon_m^{3/2} V \frac{\varepsilon_2(\omega)}{[\varepsilon_1(\omega) + 2\varepsilon_m]^2 + \varepsilon_2(\omega)^2}, \quad (9.12)$$

where V is the volume of the particle $[(4\pi/3)r^3]$, ω is the angular frequency of the exciting light, c is the velocity of light, ε_m is the dielectric function of the surrounding medium of the NPs, and ε_1 and ε_2 are the real and imaginary parts of the dielectric function of the NPs, respectively, i. e., $\varepsilon(\omega) = \varepsilon_1(\omega) + i\varepsilon_2(\omega)$. The condition for resonance is $\varepsilon_1(\omega) = -2\varepsilon_m$, if ε_2 is small and is a weak function of ω . For Au NPs in air, this can happen around $\lambda = 520 \text{ nm}$ [9.205].

In order to explain the properties of other shapes (oblate and prolate spheroidal particles), in 1912 *Gans* remodeled Mie's theory and predicted two well-defined, distinct surface plasmon modes for these metal NPs [9.206]. It is important to note that the details of the LSPR response of metal nanostructures depend on

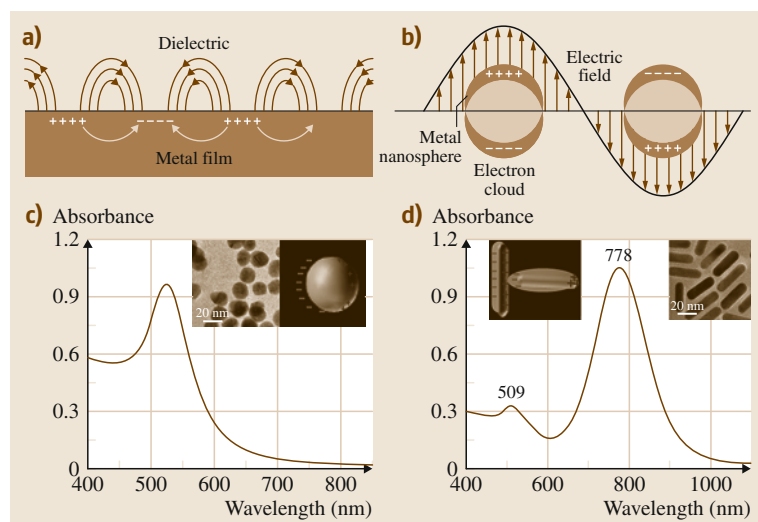

Fig. 9.11 (a) Propagation of surface plasmons on a metal surface. (b) Localized surface plasmons in metal nanospheres (after [9.198]). (c,d) Absorption spectra of gold nanospheres and NR, respectively. Corresponding TEM images of spherical and rod-shaped GNPs are shown in the inset

different variables such as size, shape, environment, dielectric function, effective mass, and electron density. **GNRs** are classical examples to demonstrate the shape-dependent **LSPR** properties. Unlike nanospheres (which have only one well-defined resonance peak), **GNRs** in their optical spectrum exhibit two bands in the visible/near-infrared (**NIR**) regions (Fig. 9.11). According to theoretical calculations, the first band near 530 nm (called transverse **LSPR**) is due to electron oscillation perpendicular to the long axis of the **NR** and the other one, appearing at a longer wavelength (called longitudinal **LSPR** mod) is assigned to an oscillation parallel to the long axis (Fig. 9.11). For anisotropic **NPs** like disks and triangular prisms, **LSPRs** are split into distinctive dipole and quadrupole plasmon modes [9.207].

The advent of new spectroscopic techniques has resulted in the capability to use surface plasmons for imaging single **NPs**. *Sonnichsen* et al. have developed a fast and flexible technique using total internal reflection spectroscopy to measure the optical scattering spectra of single metallic **NPs** [9.208]. By embedding noble metal **NPs** in an electrooptical material such as a liquid crystal, which induces a spectral shift of the particle's plasmon resonance by applying an electric field, the same group later showed that single **NP** scattering can be measured [9.209]. Using a similar method based on single-particle scattering, biomolecular recognition has also been proposed [9.210]. By this technique, **GNRs** were used as nonbleaching plasmon-based orientation sensors recently [9.211]. The polarized light scattering from individual **GNRs** was monitored in a dark-field microscope, and through observation of the rotational diffusion of gold rods attached to a glass surface, it was demonstrated that their orientation as a function of time can be determined [9.211]. This property was used for probing protein-membrane interaction as well [9.212]. Using plasmon spectroscopy, *Mulvaney* et al. recently showed that chemical reactions on single molecules can be probed [9.213]. They investigated the kinetics of atomic deposition onto a single gold nanocrystal. The electron injection and extraction during a redox reaction involving the oxidation of ascorbic acid on a gold nanocrystal surface was also monitored. Hence, for the first time it was established that direct measurement of the rates of redox catalysis on single nanocrystals is possible. It was established that **2-D** array detectors would enable the acquisition of spectra from pixels along a line in the field of view and using push-broom scanning technology, **2-D** hyperspectral images can be obtained [9.214]. *Becker* et al. selectively measured spectra of up to 20

plasmonic **NPs** per exposure using an electronically addressable mask [9.215]. However, a condition such that only a few **NPs** are present within the field of view was maintained throughout the measurements. Here for the first time they used single-particle spectroscopy to monitor the growth process of **GNPs** [9.215]. Using a grating monochromator to select a 2 nm spectral band for dark-field illumination, *Liu* et al. were able to achieve high-resolution imaging [9.216]. Au plasmonic **NPs** (**PNPs**) and **NWs** were imaged with relatively high spectral resolution and exposure time of 2 s per band. **SPR** plasmon resonance can result in a huge enhancement in the local electric field around the **GNP** surfaces [9.200, 217]. The local electric field around the **NP** surfaces can get a huge enhancement due to **SPR** [9.200, 217]. At the tip of a metal **NP** or a rough metallic surface, a highly localized and strong electric field can develop due to the interaction between the electromagnetic field and the free electrons. This results in the creation of a large electric field at the sharp tips or vertices of the **NPs**, leading to an enhancement in the Raman scattering cross-section by several orders of magnitude [9.218, 219]. This effect, known as surface-enhanced Raman scattering (**SERS**), was first observed by *Fleischman* et al. in 1974 [9.220]. This huge enhancement enables single-molecule spectroscopy, and the **SERS** activity depends on different parameters such as the size and shape of the **NPs**, the dielectric environment, the wavelength of the excitation light source, and the interparticle spacing between the **NPs** [9.221]. Shape dependence can be explained well by considering different **GNPs**. Gold mesoflowers [9.160] and triangles [9.157] were found to have higher **SERS** activity compared to their spherical analogs, owing to the higher electric field generated at the tips and edges of these **NPs**.

Chemical reactivity of **NPs** is also dependent on their surface area. These **NPs** are made-up of tens to several thousands of atoms. Each **NP** has a hybrid electronic structure having aspects of both discrete energy levels as in atoms or molecules and the band structure seen in metals. At considerably lower size regimes, i. e., below 2 nm, gold and silver **NPs** lose their metallic character substantially and start to exhibit molecular-like transitions under ambient conditions. Size ranges below 2 nm will not have the continuous band structure like bulk gold, and hence very small **NPs** (< 2 nm) do not possess continuous band structure like bulk gold and will start to demonstrate fascinating electronic properties. This aspect is briefly described in a later section (Sect. 9.8). Noble metals are considered to be the most

inert of all metallic elements. However, gold and silver NPs are known to show very good catalytic activity. In 1987, *Haruta* found that, when deposited on metal oxide supports, Au NPs smaller than 10 nm have high degree of catalytic activity [9.222]. They were found to be excellent in converting toxic carbon monoxide into

carbon dioxide at room temperature. Moreover, due to their nontoxic nature and high surface-to-volume ratio, noble metal NPs were found to be excellent candidates as catalysts for a variety of chemical reactions including hydrogenation, CO oxidation, selective oxidation, and nucleophilic additions [9.223, 224].

9.5 Postsynthetic Tuning of Properties

Tuning the properties of nanosystems is usually done during synthesis. Postsynthetically, properties can be tuned via chemical interactions or through assembly. Nanosystems that interact with chemical entities can result in either reactions or organization. Before using any system in practical applications, the reactivity of the system must be studied thoroughly. Reactions can lead to size changes, shape or morphology changes, or composite formation. All this will result in changes in properties, and through precise control over the reaction conditions, we can tune the resultant properties. Small molecular interactions can sometimes result in self-organization as well. Self-organization can sometimes result in the creation of new superstructures with novel or enhanced properties. The resultant properties can be regulated by controlling self-organization. Considerable efforts have been dedicated to this, and some of these are reviewed below.

9.5.1 Tuning Properties Through Chemical Reactions

Postsynthetic chemical transformations of nanostructures through controlled reactions are attracting growing interest. Through this method we can greatly diversify the composition of the material, or sometimes it can result in the formation of novel structures consisting of multiple components, which may not be possible through direct synthetic processes [9.225–227]. The high mechanical stress generated during the transformations enables the creation of novel structures [9.228]. The main chemical transformation reactions frequently employed in nanosystems are redox reactions and ion-exchange reactions. Redox reactions, especially galvanic displacement reactions, are some of the most studied reactions for bringing about chemical transformation in metallic nanosystems [9.229]. The reactivity of spherical NPs has been extensively reviewed [9.1, 230–232]. Hence, this section mainly concentrates on nonspherical, anisotropic particles. Moreover, the inherent diversity in the surface structure of anisotropic NPs

gives us an additional tool to regulate the reaction of these NPs and the resultant properties. Change in size or shape can greatly influence change in properties. A review of efforts that have been made to tune properties postsynthetically is presented below.

Reactions of Gold Nanorods

GNRs belong to the most studied class of 1-D nanosystems and can be taken as the best example to illustrate the reactivity of 1-D nanosystems. Optical properties of metallic NPs that originate from SPR have many application possibilities. The absorption cross-section of NPs, being orders of magnitude stronger than the strongest absorbing molecules, can impart intense color to the suspensions. In the case of isotropic spherical GNPs, a single, strong SPR absorption band in the visible region around 520 nm is observed. In contrast, anisotropic GNPs can have several plasmon resonance modes spreading from the visible to NIR region due to various excitation modes. The absorption in the NIR region has both therapeutic and imaging applications in tissues, because in this range of wavelengths, biomaterials do not have significant absorption. Hence anisotropic NPs have applications in biochemical sensors [9.233], biological imaging, and medical therapeutics [9.234]. The UV/Vis spectrum of GNRs has two characteristic maxima [9.235]. The first one, called the transverse surface plasmon resonance (TSP), is located around 520 nm and originates from the oscillation of electrons along the breadth of the NR. The second maximum is due to the longitudinal surface plasmon (LSP) resonance and is due to the oscillation of the electron cloud along the length of the NR, appearing at a longer wavelength. This band will shift to a higher wavelength region with an increase in AR (length/breadth). As mentioned earlier, the exceptional tunability of the photophysical properties of GNRs gives them an edge over their isotropic counterparts. This aspect is illustrated in Fig. 9.12. Doubling the diameter of a spherical NP only results in a minimal change in the spectral position. The sizes of GNRs are represented by a term called the AR

Fig. 9.12 UV/Vis spectra of spherical and rod-shaped GNPs indicating the tunability of anisotropic NRs (after [9.236])

which is the length divided by the breadth of the NR. A change in the AR of GNRs will change the spectrum considerably, and absorption can be tuned throughout the UV/Vis/NIR window [9.236].

The surface structures of isotropic and anisotropic GNPs differ drastically from each other. GNRs especially have an anisotropic crystal structure and have different fractions of atoms at edges, faces, and tips. Spherical GNPs are generally composed of either {111} or {100}. Usually {110} facets will be absent owing to their inherent instability compared with the other two low-index planes [9.237, 238]. However, in GNRs, the rod axis will be oriented along the {001} direction and the side faces are composed of {110} [9.239]. The tips will be mainly composed of {111} and {100} facets [9.239]. Recently, it was found that high-index planes such as {250} also can be present on GNRs [9.240].

CTAB, the surfactant used in synthesis of GNRs, has high affinity towards the {110} surface and will preferentially stabilize {110} planes, giving anisotropic surface structures for GNRs [9.239]. Due to the anisotropy of the surface crystal structure, the distribution of surfactant on the surface is also anisotropic. Due to the presence of {110} facets, the distribution of CTAB on the side faces is thicker compared with on the tips. This gives an additional tool to control the reactivity of GNRs. Incoming species attack the end faces first, and reaction starts from the tip of the NRs. Jana et al. stud-

ied the reactivity of gold spheroids and NRs prepared in the presence of silver nitrate (AgNO_3) with cyanide and persulfate [9.241]. They showed that, in the presence of cyanide, dissolution of GNRs (AR 2–5) occurs. They also found that the reaction starts at the tips and that throughout the reaction the width remains constant, leading to the formation of lower-aspect-ratio NRs. The reaction leads to the formation of spheres, which also ultimately dissolve. Time-dependent UV/Vis spectroscopy showed progressive dampening of LSP and a blue-shift indicating the decrease in the AR of NRs. After some time, only the TSP was seen, indicating the transformation of rod-shaped NPs into spheres. After the completion of the reaction, no feature pertaining to gold nanostructures remained, indicating complete dissolution of the GNRs. No clear mechanism of reaction was proposed. The reactivity of GNRs prepared in the absence of AgNO_3 was examined as well [9.242]. Here the reactivity was found to be different. Instead of decreasing the AR, dissolution occurred at various spots along the side edges. During the reaction, various pits were formed on the side faces but the length of the NRs remained the same. Here also, no mechanism was put forward for this anomalous behavior of long NRs prepared in the absence of AgNO_3 .

Charge-induced instabilities of GNRs were also studied [9.243]. They found that shape changes can be introduced in metallic NRs through double-layer charging. They found that addition of electrons in the form of reducing agents such as sodium borohydride (NaBH_4) or ascorbic acid (AA) can induce size and shape changes in small metallic NRs. Introduction of small quantities of electron densities resulted in red-shift of the surface plasmon band, and the end caps of the rods underwent increased faceting. Charge-induced faceting results in the creation of the lower-energy {111} facets. They found that more sharp edges are formed during the process. This is explained as an unusual example of Le Chatelier's principle in action. At crystallographic discontinuities, the particle electric field will be the highest. These edges can provide hot spots for driving hydrogen evolution, which catalyzes the discharge of the GNR double layer. In the presence of higher electron densities, the Rayleigh threshold is crossed and the rods fragment into clouds of smaller spheres. By the formation of spherical NPs which have predominant {111} facets, the formation of the more stable crystal facets results in the surface stress being relieved in a favorable pathway.

Reshaping GNRs by thermal treatment is also reported in [9.244]. It was found that, with increase in

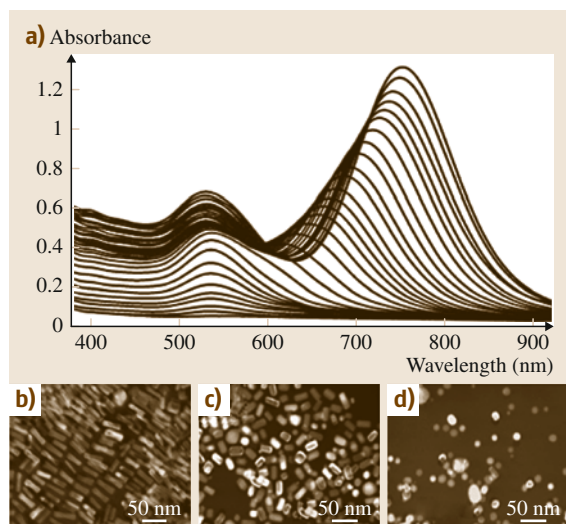

Fig. 9.13a–d Oxidation of GNRs. (a) UV/Vis spectra acquired every 1 min. TEM images of (b) initial GNRs, (c) shortened NRs, and (d) spherical particles formed due to oxidation (after [9.247])

temperature, the length of the NR decreases, resulting in decrease of the mean AR of the NRs in solution. Heating the dried NRs on the TEM grid itself did not produce a similar shape change. Hence, it was concluded that the relative instability is due to the instability of micelles capping the NRs. The calculated activation energy needed for the thermal decomposition of the micelles was found to be 21.0 ± 1.0 kcal/mol. A photon-induced shape transition process was reported by Chang et al. [9.245]. NRs were exposed to laser lines of two different frequencies, 532 and 1064 nm, and it was found that, due to photoannealing, rod-to-sphere conversion occurred. In the case of 1064 nm, new ϕ -shaped structures formed. A shape change of NRs induced by femtosecond and nanosecond laser pulses has been reported by Link and El-Sayed as well [9.246].

A mild oxidation method using O_2 which results in continuous selective shortening of GNRs was reported by Tsung et al. [9.247]. Figure 9.13a shows the UV/Vis spectral changes accompanying the oxidation. The LSP blue-shifts and decreases in intensity with oxidation, while the TSP remains at 520 nm and decreases in intensity, pointing to shortening of the GNRs. As further oxidation happens, the LSP disappears and only the TSP is seen, pointing to the formation of spherical NPs. Subsequently, oxidation also occurs, as demonstrated by the disappearance of the TSP. Similar observations were seen by TEM as well (Fig. 9.13b–d). The rate of oxida-

tion can be controlled by manipulating the temperature and acid concentration. At the same time, a strategy to fine-tune the AR of GNRs using Cu^{2+} was devised by Pradeep et al. [9.248]. The advantage of the reaction was that it can be stopped at any point of time by simply removing the heating device, and the NR of desired AR can be obtained (Fig. 9.14). It was also found that the reaction can be controlled in such a way that it starts from either the tip or the rod body by adjusting the presence or absence of the surfactant [9.248].

Spatially directed oxidation of GNRs by the Au(III)–CTAB complex has also been reported [9.249] through a redox reaction between Au^0 and $[AuCl_4]^-$. Oxidation preferentially occurs at surface sites with higher curvature such as the tips of the NRs. This peculiar oxidation was attributed to the differences in the flux of micelles to highly curved and flat surfaces of GNRs. Morphological transformation of GNRs induced by iodide formed in situ by the reaction between potassium iodide and copper chloride was reported by Wang et al. [9.250]. It was found that the thus-formed iodide could fuse GNRs in the side-by-side mode, which in turn can result in morphological transformation of GNRs to spheres. Characteristic changes in the absorption spectra with the decrease of AR, such as blue-shift of the LSP band, red-shift of the TSP band, as well as a broadening of both of these bands, were seen. They proposed this methodology for quantification of iodide without the interference of elements such as F^- , Cl^- , and Br^- , etc.

Curvature-directed oxidation of GNRs and gold pyramids was investigated by Kou et al. [9.251]. Oxidation was found to happen selectively at surface sites with high curvature. By varying the amount of H_2O_2 and HCl, the oxidation rate can be controlled. The oxidation rate increased in the order: CTBAB-stabilized Au bipyramids, CTBAB-stabilized GNRs, CTAB-stabilized GNRs. Through this method, the LSP band can be precisely controlled from 650 to 1300 nm. Overgrowth of different metals on GNR was also investigated [9.252]. They found that, depending upon the metal used, either single-crystalline or polycrystalline shells will grow on GNRs. In the case of Au and Ag, single-crystalline thin shells were formed, and for Pd the shell was polycrystalline. This was attributed to the lattice mismatch between Au and Pd. Because of the anisotropic surface structure, the competition between the overgrowth on different surface facets resulted in highly anisotropic overgrowth. Due to the strong interaction between the {110} facet and CTAB, {110} was less accessible for overgrowth compared with the {111} and {100} facets. Hence, anisotropic overgrowth occurs,

Fig. 9.14 (a) Reaction mixture at different time intervals of reaction, depiction of color changes. (b) Time-dependent UV/Vis spectra of reaction (y-axis: extinction (O.D.), y-axis: wavelength (nm)). (c–e) TEM images of the NR, nanosphere, and intermediate structure. Formation of GNRs with various aspect ratios is evident from (b) (after [9.248]) ►

and this results in the formation of dumbbell-shaped NRs.

Transverse overgrowth of GNRs by the attachment of thiol-containing molecules such as glutathione and cysteine onto their ends was reported [9.254]. It was found that, as the concentration of the Au precursor increased, the shape underwent a gradual change from rods, peanuts, and truncated octahedra to faceted spheres. The attachment of glutathione and cysteine onto the end faces blocks longitudinal growth and allows growth on the side faces, resulting in an increase of diameter while retaining the length constant. This was also found to be excellent for tailoring the plasmonic characteristics of the GNRs. By combining the selective shortening and controlled transverse overgrowth, Ni et al. devised a strategy to tune the LSP band of GNRs [9.255]. GNRs were used as the seed for making silver nanostructures, utilizing the anisotropic surface structure [9.253]. Both homogeneous and anisotropic coatings of Ag were created. This resulted in the formation of an orange slice-like shape for the Au@Ag nanocrystal. Figure 9.15 shows the UV/Vis extinction spectra during the formation of the Ag shell. The inset image shows SEM images of the structures formed. The preferential growth of the {110} facets was found to be the primary reason for the formation of the structure. Two neighboring {110} facets among the four present on the side faces grow faster compared with the others. The strong stabilization of CTAB onto the {110} facets of Ag and the minimization of the overall surface energy were given as the reasons for this selective growth. Carbó-Argibay et al. reported a chemical method for sharpening the GNRs which results in the rod to octahedron shape transition [9.256]. Rods with sharp tips and strongly faceted lateral faces were formed first. Later, they transformed into octahedrons. The growth rates on different facets were found to be different, following the order: {111} < {110} < {100}. This is believed to be due to the preferential attachment of poly(vinyl pyrrolidone) (PVP) to different body-centered cubic (bcc) facets, which alters the surface energies.

Competing growth of the Pd shell between {110} and {100} facets on the side faces of GNRs, which

resulted in the formation of rectangular Pd/Au bimetallic NRs, was reported by Xiang et al. [9.257]. The surface energy of the {110} facet is higher compared with that of {100}. Hence, a driving force to minimize

Fig. 9.15 UV/Vis extinction spectra during the formation of the Ag shell after seed addition at: (a) 0 min, (b) 2 min, (c) 4 min, (d) 6 min, (e) 8 min, (f) 10 min, (g) 12 min, (h) 14 min, and (i) 30 min. Insets: SEM images showing intermediate shapes of the Au@Ag nanocrystals during the growth process (after [9.253])

the overall surface energy by changing the morphology exists. As a result, palladium grows faster along the {110} planes than along the {100} planes. This in turn produces an enlargement of the {100} surfaces by sacrificing {110}. After some time, {110} facets disappear and a rectangular Pd shell terminated with four {100} side surfaces is formed, as illustrated in Fig. 9.16. GNRs were used as a template for synthesis of other anisotropic structures as well. Obare et al. used polystyrene and silica-coated GNRs as templates for creating hollow nanotubes [9.258]. Silica-coated GNRs (AR 13) were coated with polystyrene. Dissolution of the GNR core by the use of KCN resulted in the formation of hollow nanotubes.

Other Common Reactions on Noble Metal Nanostructures: Examples

As was discussed earlier, there is keen interest in enhancing the properties of anisotropic nanosystems by carefully engineering their structure and composition. Of the many strategies employed, galvanic replacement reactions deserve special mention. The high tunability and versatility, and the possibility to study alloying and dealloying in metallic nanostructures give these reactions utmost importance in postsynthetic design of nanosystems. Galvanic reactions are spontaneous reactions occurring when the atoms of one metal react with ions of another metal having a different electrochemical potential, whereby the metal atoms having lesser reduction potential are oxidized and dissolved into the solution, while the metal ions are reduced. Through this methodology, versatile structures such as hollow NPs, alloyed nanostructures with controllable elemental composition, and nanosystems with tunable optical properties have been created [9.259, 260]. Figure 9.17 shows such a reaction done on truncated Ag nanocubes. Another advantage of the galvanic replacement reaction is the controllability of the final morphology, which closely resembles the starting template.

Galvanic replacement reactions of Ag nanocubes have been well studied. With HAuCl_4 , Ag nanocubes are reported to show interesting galvanic reactions. The reaction can be divided into two half-reactions as follows: The half-reaction showing dissolution of metal at the anode is (standard hydrogen electrode (SHE))

The half-reaction showing reduction/deposition of the metal ions at the cathode is

Fig. 9.16 (a) Low-resolution TEM image of single bimetallic NRs. Insets show the corresponding FFT transform images. (d) Cross-section showing the morphology transition from pure GNRs to Pd/Au bimetallic NRs (after [9.257])

Hence, the total reaction is

These equations are valid only at standard conditions (at 25 °C). A change in temperature to 100 °C, the presence of Cl^- ions, and other nonstandard conditions can affect the potentials [9.261, 262].

Starting with a variety of shape-controlled nanomaterials as templates, hollow nanostructures of a variety of materials with well-defined and controllable sizes and shapes have been reported through galvanic reactions. Reaction between Ag nanocubes and HAuCl_4 where hollow nanostructures are formed has been reported [9.175]. The reaction was done at 100 °C to avoid deposition of AgCl on the surface of the nanostructures formed. Time-dependent SEM analysis showed that small pits formed on the surface of the cubes, first mainly at defect sites. As the reaction continued, these

pits expanded into the interior of the nanocubes, resulting in hollow structures. It was also found that, by controlling the reaction parameters, different structures such as nanocages, nanoboxes, etc., could be generated using this methodology. The creation of nanocages with controllable pores was possible when different facets were present on the surface of the starting Ag nanocubes [9.263]. Galvanic reaction on 42 nm Ag nanocubes with truncated corners having six {100} facets and eight {111} facets, and some {110} facets at the truncated parts, resulted in the formation of final pores selectively on the {111} facets at the corners. After the replacement reaction, the pores found at all eight corners (consisting of {111} facets) were uniform in size and shape. The facet-selective reactivity observed is explained as being due to the preferential binding of PVP to {100} facets of Ag compared with {111} facets, thereby making the {111} surface more exposed for reactions.

Galvanic reactions normally preserve the morphology of the starting materials. However, when the facet-selective reaction was started with 24 nm spherical Ag particles, this morphology changed to octahedrons [9.266]. Starting Ag particles had {111} and {100} facets. As discussed above, the pitting reaction happened on the {111} facet and deposition of Au on the {100} facet. Due to the smaller size of the particles, this resulted in a change in morphology. A similar transition was seen in the case of 11 nm Ag spheres as well [9.267]. Similar reactions are also applicable for polycrystalline materials [9.268–270].

Hollow nanotubes can also be made using an analogous method. Ag NWs having five twin-planes along the length of the wire together with a pentagonal cross-section were treated with HAuCl_4 [9.271]. Multi-walled structures such as nanorattles, multi-walled nanoshells, and multi-walled nanotubes can be made using this reaction [9.77, 271]. By electroplating, a thin layer of pure Ag was coated on the surface of Au-Ag alloy particles, and the consequent reaction resulted in multi-walled structures. Using a comparable strategy, a single-step, large-scale methodology for the production of nanoframes of different morphologies was reported by Sun et al. [9.77].

The difference in surface energies between common facets of face-centered cubic (fcc) metals were used for fabricating hollow Au-Ag octahedrons containing GNRs [9.272]. The difference in surface energy resulted in an uneven growth rate and a complete change in the morphology. GNRs to begin with had {111}, {100}, and {110} facets. After deposition of Ag, all the rods

Fig. 9.18 (a) Schematic summarizing the formation of cubic Au nanoframes by treating Ag nanocubes with HAuCl_4 to form Au-Ag nanoboxes (b), and then etching with ferric nitrate to form thin-walled nanoboxes (c) and eventually cubic nanoframes (d). Inset scale bars are 50 nm (after [9.265])

transformed into Au@Ag octahedrons capped by {111} facets. When the resultant particles were treated with excess HAuCl_4 , hollow Au-Ag octahedra containing GNRs were formed. A similar reaction has been observed out in organic media as well.

Galvanic reactions of Pd NRs with HAuCl_4 did not produce hollow structures. Instead, solid tadpole-like structures having a Pd tail and an Au head were formed [9.273]. As the reaction proceeded, Au was deposited first at one end and then both ends. The selective deposition was attributed to electron–electron repulsion, which pushes the electrons generated during Pd oxidation to either ends of the rod, resulting in the

reduction of Au^{3+} . After some time, the Au head increased in size and eventually fell off the structures. A similar study of polycrystalline Pd rods resulted in a nonrandom alloy with an Au-rich core and a Pd-rich shell. A similar morphology was formed when Co NRs were treated with Au precursors as well [9.274].

Introduction of a wet etchant such as ferric nitrate ($\text{Fe}(\text{NO}_3)_3$) can influence the galvanic reaction between Au and Ag [9.276, 277]. This enables removal of Ag without deposition of Au, resulting in better control of wall thickness, composition, and resultant optical properties. Ag nanocubes were treated with HAuCl_4 first, which resulted in the formation of small pits. On treatment with $\text{Fe}(\text{NO}_3)_3$ solution, thin-walled nanoboxes were formed. As the concentration of $\text{Fe}(\text{NO}_3)_3$ added increased, the thin-walled nanoboxes were converted to nanoframes. This transition was attributed to the higher susceptibility of $\{100\}$ facet towards etching (Fig. 9.18).

Due to their catalytic applications galvanic replacement of Ag nanocubes with Pt and Pd precursors have been well studied [9.278]. Reaction between 50 nm Ag cubes and Pt precursor resulted in hollow structures with rough exterior. This was attributed to the lack of miscibility between Pt and Ag at the reaction temperature (100°C), but when the reaction was done with Pd, the surface of the structures formed was smooth. However, the reaction never went beyond the nanobox stage. When the galvanic reaction was done with two or more metal ions, the order of addition was found to influence the resultant morphology [9.78]. In the case of Au and Pd reaction with Ag nanostructures, addition of Pd before Au resulted in products with large pores. However, first reaction with Au and subsequent reaction with Pd resulted in solid walls. In the case of Au, there was a difference in reactivity between $[\text{AuCl}_4]^-$ and $[\text{AuCl}_2]^-$. The striking difference between Au(I) and Au(III) was the early disappearance of the pinhole in the case of Au(I), due to the larger amount of Au deposited for the same amount of Ag being dissolved. Structure-wise, in the case of Au(I), the walls of the nanocages were thicker compared with those formed for Au(III).

An epitaxial growth process by which Au nanooctahedra were changed to Pd and Ag nanocubes was reported by Fan et al. [9.279]. Au nanooctahedra were used as seeds, and through the use of a seed-mediated growth method, shape transition was realized. The formation of an asymmetric hollow structure from a heterometallic NR by partial galvanic reaction was demonstrated by Seo and Song [9.275]. They found that asymmetric single-hollow or symmetric double-hollow

Fig. 9.19a–h Schematic representation of the galvanic replacement in Ag-Au-Ag heterometallic NR. SEM and TEM (insets) images of (a) original heterometallic NR and (b–d), (f), and (g) hollow structures at different concentrations of Au^{3+} . (e, h) Energy-dispersive x-ray spectroscopy (EDAX) line profiles along the long axes of the hollow structures (after [9.275])

NRs could be generated from Ag-Au-Ag heterometallic NRs. The breaking of symmetry was a result of random pit formation on the Ag end. The reaction scheme and the structures formed are shown in Fig. 9.19. Production of triangular gold nanorings by galvanic replacement reaction of ultrasonically synthesized Ag nanoplates was reported by Jiang et al. [9.280]. The nanoplates and nanorings were highly single crystalline and had $\{111\}$ planes as the basal planes.

The diffusivity difference between metals can give rise to the formation of hollow structures by a phenomenon known as the Kirkendall effect (KE). If the inner material diffuses outwards faster than the rate at which the outer material diffuses inwards, voids will form. In nanosystems, such an effect can result in the formation of hollow structures. Several reports exist in this regard [9.267, 281–284]. Recent studies reveal that the formation of some of the hollow structures discussed above through galvanic replacement reactions can also

have a contribution from the KE [9.283]. Reaction between cobalt nanocrystals in solution with oxygen and either sulfur or selenium can result in the formation of hollow nanocrystals through the KE [9.281]. Recently, a size-dependent nanoscale KE observed during the oxidation of nickel NPs was reported by Railsback et al. [9.285]. Depending upon the size of the NP, either single-pored or multipored NiO nanostructures were formed. It was found that the fast self-diffusion of Ni compared with its rate of diffusion through the NiO shell resulted in the single-pore structure. When the diffusion was not fast enough, multiple pores resulted.

9.5.2 Modification of Properties – Formation of Superstructures

Tapping the incredible properties exhibited by NPs into useful applications is challenging when one is working with individual NPs. Assembling them into well-arranged superstructures is one of the ways to make use of these systems in modern day science and technology. Assemblies of NPs are important for many fruitful applications. Functionalization of noble metal NPs is comparatively easier and this makes them attractive candidates for making diverse superstructures. Creation of their one, two, or three-dimensional assembled structures can enhance the properties or can sometimes give rise to novel improved properties due to the effective coupling of different domains. Noble metals (mainly gold and silver) owing to their biocompatibility, tunable optical properties, and easy synthesis, have been extensively used to create superstructures that are useful in studying various properties including SERS, metal-insulator transitions, interplasmon coupling, etc.

Assembly can be brought about by using molecular linkers, templates, or spacers in well-organized periodic one, two- or three-dimensional superstructures. For spherical NPs solid superstructures called particle crystals or SLs [9.286–288] can be generated via bottom-up or top-down approaches. A high degree of monodispersity is the prerequisite for making such SLs over a long range. The changes in properties of individual NPs in the collection can be understood by studying these structures. For example, changes in optical properties such as interplasmon coupling and changes in transport properties including metal-insulator transitions, etc., can be understood in a better way by studying the properties of SLs [9.286]. Various strategies such as electrostatic self-assembly, solvent evaporation on a substrate, self-organization at interfaces, covalent and hydrogen bonding, biochemical interaction, van der

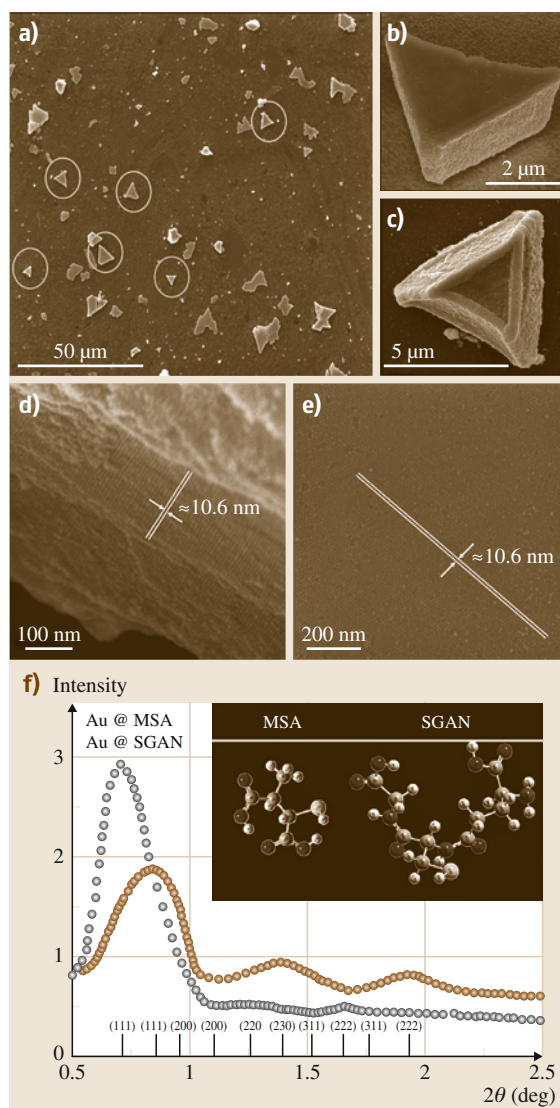

Fig. 9.20 (a–e) SEM images of superlattices made of GNPs at various magnifications. (d,e) Clear images of large area ordered arrays of NPs. (f) Small-angle x-ray scattering showing the regular array of atoms in SLs. From the authors' laboratory

Waals and dipole interactions, etc. [9.289], have been utilized to create SLs of GNPs. Several well-written reviews are available on this topic [9.289, 290].

Digestive ripening, the SMAD method, and hydrogen-bonding methods are used extensively to create SLs [9.289]. Thiol-protected GNPs synthesized by the SMAD process upon digestive ripening will

spontaneously form 2-D and 3-D SL crystals via self-organization. Changing the pH of the solution by the addition of acid ($\text{pH} \approx 2$) resulted in the organization of MSA acid-protected GNPs into beautiful 3-D structures [9.287, 291]. The formation of hydrogen bonding between the dicarboxylic acid moieties present on the adjacent NPs drive the assembly formation. Formation of a brown mirror-like appearance on the air/water interface after a few days indicates SL formation [9.292]. Diverse morphologies such as triangles, hexagons, etc., were adopted during the crystal formation. Some representative SLs formed by these interactions are shown in Fig. 9.20.

Spherical particles that are isotropic will experience the same interactions in all directions in a 3-D assembly and the resultant effect as well as collective properties will be the same. Only the extent of interaction and hence the change in properties will vary depending upon the dimensionality of the assembly. Unlike isotropic NPs, the inherent anisotropy of anisotropic NPs adds a directional dependence on the assembly and the consequent interactions between NPs. A variety of factors plays seminal roles in assembling NPs in an ordered manner, without the formation of complex 3-D aggregates. The following section reviews different assemblies of various nanostructures and various forces inducing such assemblies.

Assembly of Gold Nanorods

The crystal structure and crystallographic planes present on the NP surface plays important part in regulating their assembly. Unlike spherical NPs, which have an isotropic crystal structure entirely composed of either $\langle 111 \rangle$ or $\langle 100 \rangle$ planes, the surface structure of anisotropic NPs are different. GNRs are classical examples of this anisotropic surface crystal structure. The GNR surface is highly anisotropic consisting of different facets (Fig. 9.21a,b) [9.239]. The edges (side faces) of GNRs are constructed by $\langle 110 \rangle$, and their tips consists of either $\langle 111 \rangle$ or $\langle 100 \rangle$ facets [9.239]. Due to this anisotropic crystal structure, the distribution of surfactant molecules (the CTAB bilayer coverage) on the surface of GNRs will also be anisotropic, and the bilayer will be thicker on the side faces due to the higher affinity of CTAB towards $\langle 110 \rangle$ facets. A lattice-resolved image of a GNR showing the specific planes is given in Fig. 9.21b.

Anisotropy in the crystal structure and in surface reactivity can be used as tools for selective functionalization of GNRs to bring about specific interactions between GNRs leading to different types of assem-

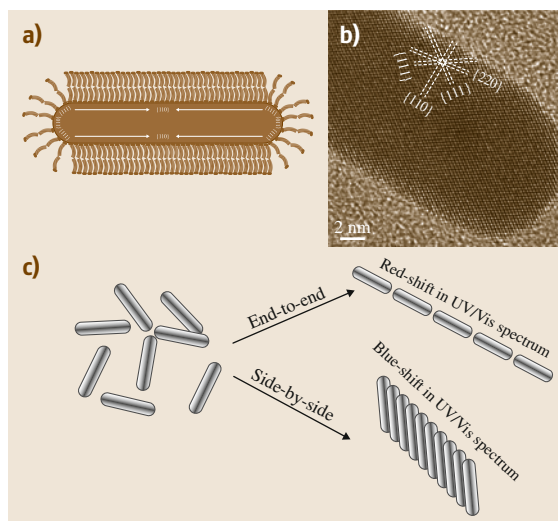

Fig. 9.21 (a) Schematic of a single GNR. (b) High-resolution TEM (HRTEM) image showing the different crystal planes and lattice structure. (c) Schematic showing the different ways of arranging the NRs

bled structures. Because the tips of GNRs are less populated with CTAB they are more susceptible to functionalization strategies and can thus trigger end-to-end interactions to form linear chains where GNRs are connected in an end-to-end fashion. The shape anisotropy of GNRs opens up another type of linear assembly where the sides of the NRs interact with each other (termed as side-to-side assembly). The free energy of bilayer stabilization between CTAB molecules is 6 kJ/mol per two methylene groups and hence the removal of CTAB from the side faces is rather difficult [9.293]. Hence, to bring about the functionalization of this face, rigorous procedures must be followed. The possible interactions and different kinds of resultant assemblies are pictorially depicted in Fig. 9.21c. Theoretical studies have established that side-by-side assembly leads to a blue-shift in the UV/Vis spectrum, whereas end-to-end assembly imparts a red-shift [9.294]. The extent of the shift in the spectra depends on the extent of assembly. For example, in a 2-D or 3-D assembly where multiple interactions are present, the resultant shift can be a combination of all of these interactions.

Spontaneous assembly without any external aid is often called self-assembly. GNRs are known to self-assemble under optimum conditions such as concentration, pH, ionic strength, etc. Controlling the interactions between the constituents can lead to mod-

ification of self-assembly. Generally, environmental conditions such as pH and ionic strength are modulated for this purpose. Then the process will be termed *programmed self-assembly*. The assembly process can be controlled by chemical modifications or functionalizations as well. Surface functionalization of GNRs with specific molecular groups can result in precisely programmed self-assembled structures. Due to its simplicity, versatility, and low cost, programmed self-assembly with functionalized NRs is used extensively for nanofabrication purposes. One of the disadvantages of this strategy is that it normally produces ordered structures with small area and does not allow control over the design or interparticle distance in the NR architecture. Also, once triggered, further manipulation of the assembly is rather difficult. However, a better understanding of the system and the advent of new techniques are helping us to overcome these limitations. Programmed assembly can be brought about using a wide variety of operating forces, by changing the functionalizing molecules. The operating forces involved in the assembly can be covalent, hydrogen bonding, electrostatic, biochemical interaction, van der Waals, dipole interactions, etc.

The following section illustrates a brief review about the different kinds of assemblies and the operating forces leading to the assembly, taking GNRs as the example.

Self-Assembly of Gold Nanorods upon Solvent Evaporation

GNR suspensions are stabilized due to the electrostatic repulsion between the head groups of CTAB (the stabilizing bilayer) on adjacent rods avoiding aggregation. Removing excess surfactant by centrifugation and at optimum concentration, pH and ionic strength, the hydrophobic–hydrophobic interaction between the CTAB tails can compensate the electrostatic repulsion facilitating the assembly of NRs where the distance between the NRs depends on the compensation of the above-mentioned interactions. Therefore, NRs form assembled structures with an optimum separation between NRs upon solvent evaporation, with all forces being compensated. In 2000 Nikoobakht et al. made one of the first attempts to study the self-assembly of GNRs [9.295]. GNRs prepared by electrochemical methods ($AR \approx 4.6$) were centrifuged at 14 000 rpm and were resuspended in water. The sample was diluted to an optical density of 1.5–1.7. A 1 : 1 solution of the above suspension and 0.1 M NaCl solution was made and was dropcasted onto a TEM grid as shown in the

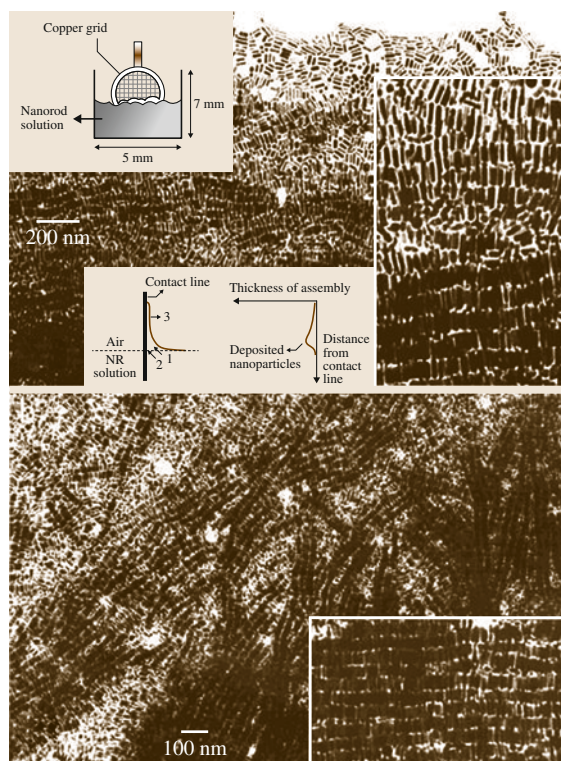

Fig. 9.22 Electron micrograph showing border of the self-assemblies. The thickness increases from *top* to *bottom*. The *insets* show magnified parts of the assembly. *Inset top left*: scheme of the deposition method (after [9.295])

inset of Fig. 9.22. Long-range (over micrometer areas) 1-D, 2-D, and 3-D assemblies of GNRs were formed on the grid upon solvent evaporation. Here the electrolyte (NaCl) was used to form the assembly. Later it was found that even without the use of electrolyte, removal of excess CTAB can result in self-assembly at appropriate NR concentrations [9.293]. It is also reported that liquid-crystalline assemblies of large-aspect-ratio GNRs will form when the as-prepared rods are centrifuged to remove associated spherical particles and are redispersed in an optimum concentration of CTAB (1–100 mM). The assembly was studied in detail using UV/Vis and small-angle x-ray scattering (SAXS) measurements.

Assembly Involving Biological Interaction and Bio-Recognition

Functional entities in biology are almost entirely assembled structures and the operating forces involved are very specific. GNRs have been assembled using such

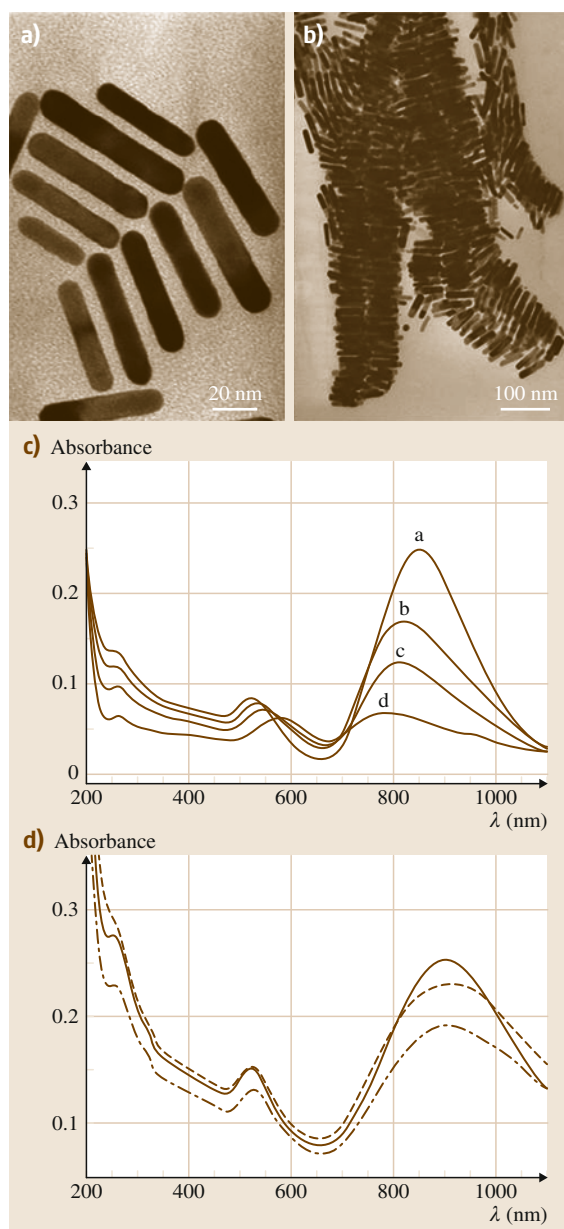

Fig. 9.23a–d TEM images of bundles of DNA-linked GNRs. The three-strand (a) and two-strand (b) DNA linking systems. UV/Vis spectra of (c) a suspension of non-complementary DNA functionalized NRs and (d) the two-strand NR system before (solid line) and after (dashed line) duplexation at 25 °C. The dashed curve represents the spectrum after melting the DNA above 60 °C (after [9.296])

interactions as well. The first effort in this direction was made by *Dujardin et al.* [9.296]. In this work, NRs were functionalized with thiolated DNAs. Assembled structures were formed upon addition of duplex DNA into the above mixture. Figure 9.23a,b shows TEM images of the assembled structures and the associated UV/Vis spectral changes during the assembly (Fig. 9.23c,d).

End-to-end assembly of GNRs, surface-functionalized with mercaptoalkyloligonucleotide, was brought about by the addition of a target oligonucleotide [9.297]. Here, the thiol groups in the mercaptoalkyloligonucleotide binds to the ends of the NRs, which further assemble in end-to-end fashion through hybridization with the target oligonucleotide. *Chang et al.* utilized the specific binding of an antibody to an antigen to form an oriented assembly of GNRs in solution through a biomolecular recognition system [9.298]. In this work, thioctic acid (TA), used as a binding agent, was made to specifically self-assemble onto GNR tips. The conjugation of TA with various immunoglobulins (Ig) or other biomolecules resulted in the GNR to assemble. *Wang et al.* utilized a similar strategy to detect proteins such as IgG [9.299]. Compared to the spherical counterparts (detection limit 0.1 µg/ml), an enhanced detection limit of 60 ng/ml was shown by the NR assembly.

The biotin–streptavidin interaction is one of the most specific and strongest noncovalent interactions known in biology. Utilizing this interaction, a preferential end-to-end assembly of GNRs was fabricated. First, GNRs were surface-functionalized with biotin disulfide and the subsequent addition of the streptavidin linker gave GNRs assembled preferentially in end-to-end fashion [9.300]. A simple and versatile approach for end-to-end assembly of GNRs was reported by *Huang et al.* This strategy involved the specific molecular recognition between thymine-rich (T-rich) oligonucleotides and mercury(II). The high specificity of the oligonucleotide improved the selectivity of the process [9.301].

Assembly Involving Covalent Bonding

Longitudinal assemblies of GNRs were fabricated by the interaction of GNRs and α,ω -alkanedithiols of varying chain lengths, and the mechanism, structure, as well as changes in properties were investigated using absorption spectroscopy and TEM by *Thomas et al.* [9.302]. A decrease in the longitudinal plasmon absorption was observed upon addition of dithiols. The simultaneous appearance of a new red-shifted band above a critical dithiol concentration resulting from the interplasmon

(l) Cartoon representation of various superstructures formed from Au NRs in the presence of different concentrations of DMSA. From the authors' laboratory (after [9.303])

coupling in the assembled NRs was also observed. The presence of clear isosbestic points in the time-dependent absorption spectrum, and TEM investigations proved the formation of dimers, indicating the existence of a dimerization step in the chain-up process. It was also understood that the process is not diffusion controlled but activation controlled with large activation energy [9.302].

Assembly Through Hydrogen Bonding

The cooperative intermolecular hydrogen bond formed between two thioacids anchored onto the end faces of GNRs was utilized to precisely control the longitudinal assembly and modulate the plasmon coupling. Adjusting the concentration of thioacids added into the mixture resulted in the modulation of plasmon band positions. An increase in concentration of thioacids produced a plasmon shift to a higher wavelength. Precise tuning of the optoelectronic properties is possible through this method [9.304]. Recently, hydrogen-bonding-directed assembly of GNRs in aqueous solution was investigated by Ni et al. [9.305]. Theoretical as well as experimental investigations of the mechanism behind the formation of end-to-end assemblies of GNRs modified with bifunctional linking molecule were made in this study.

Assembly Through Electrostatic Forces

Electrostatic interactions are one of the most common forces encountered in the living world and in assemblies. Electrostatic forces between amino acids anchored onto GNR surfaces were utilized to assemble NRs [9.306]. Two thiol containing amino acids, namely cysteine and glutathione were added to the GNR solution. Due to the thiol-gold affinity, they became anchored onto the GNR end faces and the electrostatic interaction between adjacent amino acids on separate GNRs resulted in the preferential longitudinal assembly (Fig. 9.24). This was manifested by a red-shift of the LSP. This change in the plasmonic characteristics was used for specific detection of cysteine and glutathione at micromolar concentrations. Gold bipyramids and rods were assembled into different types of nanonecklaces using a similar methodology by Zhang et al. [9.307].

The time-dependent shift in LSP at a specific concentration of assembly-inducing agents was always constant and it was not precisely controllable in any of the above methods. Kawamura et al. reported a more controllable fabrication method for GNRs assembly, in which the shift of the LSP can be stopped at a desired

point to obtain a stable suspension with a desired absorption range [9.308]. A gradual red-shift of the LSP was observed upon addition of sodium citrate to GNRs, which can be stopped at any point simply by the addition of CTAB to the reaction mixture. The preferential adsorption of citrate anions onto the end faces of the GNRs, which results the neutralizations of the surface charge of the GNR ends, triggers the end-to-end assembly of the GNRs. High AR GNRs (AR of 16) assembled in an end-to-end fashion upon decreasing the CTAB concentration and the assembled GNRs became welded at their connecting points upon a further decrease of the CTAB concentration [9.308]. A pH-dependent self-assembly of GNRs into ordered structures using adipic acid was reported by Orendorff et al. [9.309]. Here, the electrostatic interactions between the cationic surfactant bilayer around the NRs and the negatively charged deprotonated adipic acid result in pH-dependent self-assembly of the NRs into 2-D ordered structures. A similar but more refined strategy to assemble GNRs into 1-D, 2-D, and 3-D superstructures was reported by the authors of this chapter (Fig. 9.25). The addition of dimercaptosuccinic acid (DMSA) to the NR solution-induced self-assembly of the latter into 1-D tape-like, 2-D sheet-like, and 3-D SL-like structures depending on the DMSA concentration. A smectic structure where the NR long axes are parallel to each other was found to be followed throughout the assembly process. Different parameters that determine the quality of the assembly including DMSA concentration, pH, and monodispersity of the sample were studied. Immediately after the addition of DMSA to the NR solution, UV/Vis spectral changes were observed. The peak position was found to be stable (after the initial shift) even after 24 h of incubation. A gradual shift was observed for the LSP, while the TSP remained unchanged. An increase in concentration of DMSA resulted in an increased red-shift. There was a marginal increase in width of the LSP as well. At lower concentrations, a longitudinal assembly formed was transformed into a lateral assembly upon increase of the DMSA concentration. As the concentration was increased, the assembly changed from 1-D tape-like to 2-D sheet-like, and finally to 3-D SL-like structures. Perpendicular arrangement of NRs (NR long axis perpendicular to the TEM grid) was also seen at places. At lower pH (below the pK_a of DMSA) where DMSA molecules are not ionized no assembly was produced. Detailed investigation indicated that charge neutralization of the NRs by the carboxylic group of DMSA was found to be the principal reason for such an assembly, while the mercapto groups render additional stability to

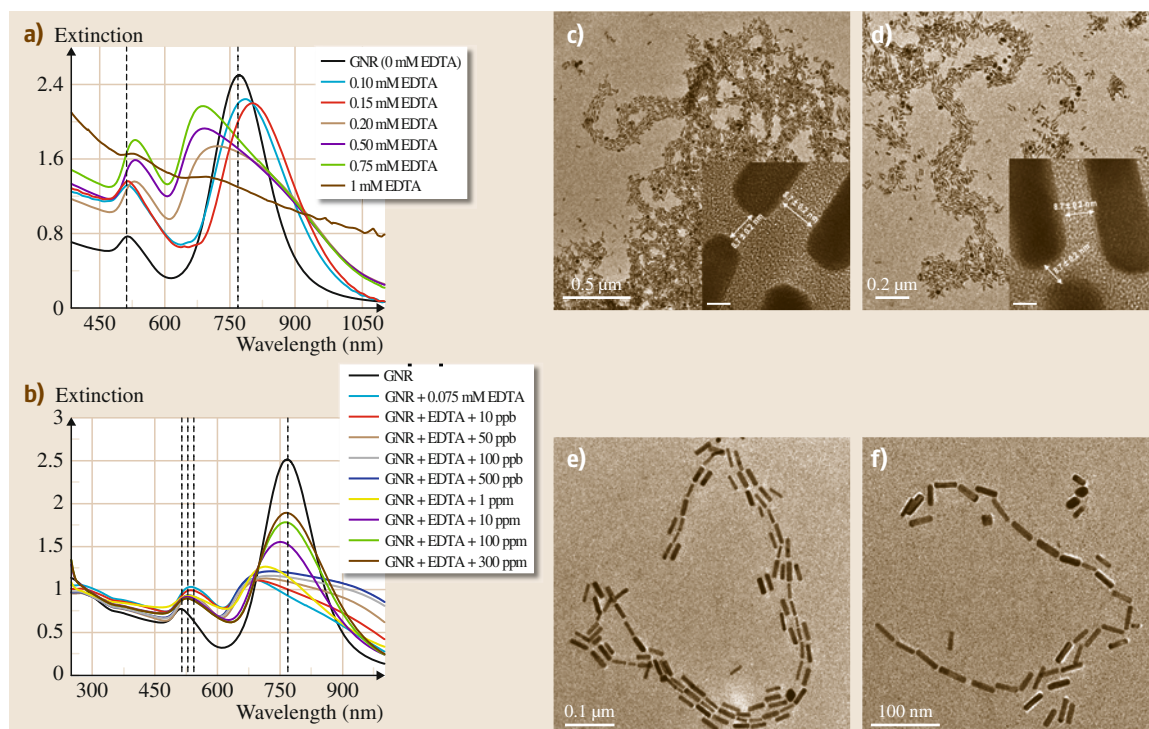

Fig. 9.26a–f UV/Vis spectral changes of the assembly (a) and disassembly (b) processes. TEM images of assembly and disassembly by EDTA–Pb²⁺ interaction (c–f). From the authors' laboratory (after [9.303])

the superstructure. A mechanistic model of the assembly has also been proposed [9.310].

Electrostatic assemblies are difficult to manipulate once they have been formed. However, recently a strategy for the reversible assembly and disassembly of GNRs was also devised [9.303]. A labile ligand ethylenediaminetetraacetic acid (EDTA) was used. The disassembly followed a peculiar pattern by forming bundled chains and then single chains before forming discrete NRs. It was also observed that the assembled structures are highly SERS in nature and through use of the disassembly method SERS activity can be tuned. Figure 9.26 illustrates the UV/Vis spectral changes of the assembly (Fig. 9.26a) and disassembly (Fig. 9.26b) process. The TEM images of the disassembly also can be seen (Fig. 9.26c–f) [9.303].

Gold Nanorod Assembly Involving van der Waals and Dipole Interaction

Changing the hydrophilic nature of the GNR surface (due to the presence by of CTAB) to hydrophobic by treating with mercaptopropyltrimethoxysilane (MPS) and subsequently octadecyltrimethoxysilane (ODS) can

induce formation of assembled structures. Well-ordered 2-D or 3-D superstructures of hydrophobic NRs on a substrate by solvent evaporation technique was reported by Mitamura et al. [9.311]. The concentration of the NRs controlled the 2-D assemblies and at lower concentration, the NRs assembled parallel to the substrate. Upon increasing the concentration, NRs started to stand on the substrate to form perpendicular assemblies forming hexagonal arrays. 3-D assemblies with a hexagonal close-packed structure due to their side-by-side interaction leading to lamellar structure (over small range) were observed when the NR sample was converted into a solid state.

Nakashima et al. devised a strategy to prepare surface-directed, lateral or perpendicular GNR assemblies [9.312]. This was achieved by anchoring a home-made peptide, 1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanol (DPPTE) onto the GNR surface. The drying method and the hydrophilic or hydrophobic nature of the Si surface influenced the form of self-assembled superstructures (Fig. 9.27). Driven by intermolecular interactions of surface-anchored lipids, the GNR–DPPTE hybrid formed characteristic 1-D and 2-D self-assemblies

Fig. 9.27a,b TEM images of assemblies of hydrophobic GNRs arranged (a) parallel and (b) perpendicular to the substrate. Insets are the corresponding high magnification images (after [9.311])

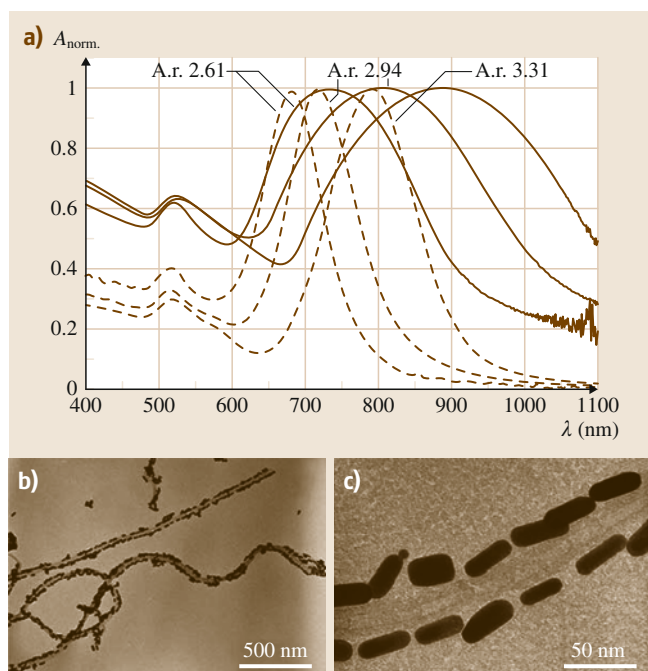

Fig. 9.28 (a) UV/Vis spectral changes and TEM images of GNRs (average AR 2.94) assembled on MWNTs (average diameter 30 nm) at different magnifications (b,c)

upon controlled drying process. Solvent evaporation from the sample drop in combination with interfacial hydrophilicity or hydrophobicity induced a variety of self-assembled structures. Walker and Gupta reported a reversible, pH-dependent strategy to form end-to-end assembly of GNRs functionalized with disulfide-modified poly(L-glutamic acid) [9.313].

Changes in pH of the medium-induced corresponding changes in the secondary conformation.

Recently, GNRs were assembled, disassembled, and reassembled by Chan et al. who used a bis(terpyridine)–metal connectivity [9.314]. A special molecular moiety

(disulfide-modified terpyridine) 2-M(II) ($\text{M} = \text{Fe}$ or Cd) was used as interconnectors to form end-to-end linear and branched assembly of GNRs into multicomponent structures. Basic conditions destabilized the prepared (terpyridine) 2-M(II) complexes and the addition of NaOH resulted in disassembly. When Cd was used to induce the assembly, the complexes formed were labile and the resultant assembly was also found to be labile. At low concentrations of Cd, assemblies were formed and in the presence of excess Cd(II) ions, they disassembled. Upon addition of Fe(II) to this disassembled system, they again reassembled into end-to-end chains. This also could also again be disassembled by a mere change in the pH as mentioned above [9.314].

Assembly on Templates

Assembly of NPs on templates is a widely utilized strategy. Correa-Duarte et al. was the first group to form GNR superstructures via this approach [9.315]. Multi-walled carbon nanotubes (MWNT) were used as the templates in this work. First the CTAB covering on the GNRs was interchanged with PVP. Then, MWNTs were coated with a polyelectrolyte, mainly polystyrene sulfonate (PSS), followed by poly(diallyldimethylammonium chloride) (PDDA). This wrapping resulted in the production of adsorption sites on the carbon nanotubes (CNTs) where GNRs could be deposited electrostatically. A preferential end-to-end assembly of GNRs, forming a string-like alignment (Fig. 9.28) resulted through this method. A broadened absorption feature exhibited by the superstructures indicated the formation of end-to-end assembly and the resultant plasmon coupling between neighboring NRs. It was also noted that these NRs can serve as a label to monitor the alignment of CNTs within polymer films [9.315, 316]. Using drying droplets as the templates, rings of NRs were fabricated by Zubarev and Khanal [9.317]. A simple and quantitative model for the formation of GNR rings was also described. Here, condensed water droplets from humid air on the surface of nonpolar solvents acted as templates for the spontaneous assembly of hybrid gold–polymer core–shell NRs.

Pradeep et al. reported the use of microgels as a template for a solution-phase method for assembling NRs into a hexagonal pattern [9.318]. First, poly(*N*-isopropyl acrylamide) (PNIPAm) microgels coated with GNRs were synthesized. For this purpose, microgels loaded with CTAB-coated GNPs of 4–5 nm size (used as seed particles) were added to the growth solution used for the seed-mediated growth method for GNRs. This helped in achieving the required population of

Fig. 9.29a,b TEM images of the GNR-PNIPAm composite. (a) Large-area image of the hexagonal pattern with defect sites marked with *dashed circles*. (b) Higher magnification image of a single cell of the hexagonal pattern confirming that the anisotropic structures sitting on the microgels are GNRs. From the authors' laboratory (after [9.318])

NRs on the microgels (Fig. 9.29a,b). These NR-loaded microgels were allowed to self-assemble to obtain a hexagonal pattern (Fig. 9.29c,d). Similar experiments performed with NP-coated or prefabricated NR-coated microgels did not give such hexagonal patterns because of the reduced number density of NPs. The interpenetration and interlocking of the NR structures were thought to be the reason for the formation of these patterns [9.318]. Fava et al. made use of the affinity of NRs for PNIPAm-based microgels for their sequestering by cationic, anionic, and close-to-neutral-state microgels [9.319]. Cationic, anionic, or near neutral microgels were fabricated by adjusting the pH of the solution. Sequestration of GNRs occurred independently of the charge of the microgels when added to the above solutions. This indicates that electrostatic interactions alone do not govern the loading of microgels with NRs. Electrostatic interactions and subsequent coating of silica with controllable thickness was used to assemble GNRs by Wang et al. [9.320].

Assembly on Substrates

Assembly of nanostructures on suitable substrates has the extra edge that it can be directly used for applications. Mieszawska et al. reported a methodology for directly growing highly aligned GNRs on a NH_2 -functionalized Si(100) substrate with a remarkable degree of parallel alignment over large areas [9.321]. When a similar reaction was carried out on amorphous glass no assembled structure was observed, which pointed towards the importance of having a crystalline structure. However, throughout the sample, the alignment direction varied and no direct correlation between

the arrangement of Si atoms and GNR assembly was seen. Hence it was concluded that the crystallinity of the substrate will not affect the direction of assembly. The exact mechanism of the assembly is still not well understood. Control experiments with mercaptopropyltrimethoxysilane (MPTMS) – and (aminopropyl) triethoxysilane (APTES) functionalized, or bare Si(100) did not produce any assembled structures, which indicates the importance of surface chemistry. However, the exact role of the amidation reaction in the alignment is not yet clear. Mieszawska et al. observed alignment on acetic and succinic acid surfaces implying the minimal role played by surface hydrophobicity [9.321]. End-to-end alignment of phosphatidylcholine-passivated GNRs adsorbed on polyanion-modified glass substrates were demonstrated by Yamada et al. [9.322]. Zhang and Imae successfully used a patterned silicon substrate with hydrophobic stripes for growing gold NR SLs [9.323]. Perpendicular SLs were also fabricated by this method. The most important factor governing the assembly was the substrate surface. GNRs should be either positively attracted or at least not repelled by hydrophobic surfaces in order to obtain a well-defined assembly. GNRs stayed in solution when the silicon substrate was hydrophilic. Another important criterion was the monodispersity of the sample devoid of particles without shape difference. Zareie et al. reported a protocol to directly grow end-to-end assembled long chains on a substrate embedded with a mixed self-assembled monolayer (SAM) that had been functionalized with streptavidin [9.324]. Assemblies extending over a micrometer in length with 5 nm inter-rod separation were obtained by this process.

Assembling by Polymer Tethering

A novel strategy where self-organization of GNRs into a predefined pattern by attaching multiple polymer arms termed *pom-poms* was reported by Kumacheva et al. [9.319, 325, 326]. NRs that are end-terminated with polystyrene (PS) when dispersed in dimethylformamide (DMF)/water mixtures tend to self-assemble into higher-order structures. The length and distribution of the PS molecules between the ends and the longitudinal facets of the NRs controls the ordering. Changing the structure of the polymer pom-poms also can modulate the assembly. Depending upon the variation in the molecular weight of the polymers and their relative location on the long side of the NRs, various kinds of NR assemblies namely bundles, bundled chains, and chains involving side-by-side and end-to-end assembly were generated. By changing the concentration of

water in the system, one form of assembly can be changed to another one. It was also understood that the evolution of the self-assembled structures of GNRs end-terminated with PS occurs through competition between side-to-side and end-to-end assemblies. This competition is due to the difference in solubilities of the PS and CTAB-coated metal blocks in the solvent mixture. The tendency to side-to-side aggregation was found to be dominant over most of the compositional range. The above tendency was reduced at high DMF or water content and at very low THF/DMF weight ratios [9.319, 325, 326].

Layer-by-Layer Assembly of Gold Nanorods into Gold Nanorod Films

Yun et al. recently developed a protocol for assembling GNRs into 2-D arrays at a water/hexane interface without the aid of any linker molecule [9.327]. In this method, aggregates of GNRs with a relatively clean surface and controlled NR density were obtained and the film thickness can also be controlled systematically. Because GNRs are hydrophilic, they have a contact angle of $< 90^\circ$ at a water/hexane interface and they will always remain in the aqueous phase. However, when their contact angle is approximately equal to 90° , these particles start to adsorb to the water/hexane interface. A medium with high dielectric constant can separate the charged particles from each other. However, the introduction of a miscible solvent with lower dielectric constant will result in a decrease in the dielectric constant of the medium. Consequently, the surface charge of the particles will also be decreased as a function of the amount of miscible solvent added. When ethanol (with a lower dielectric constant) is added to the water/hexane interface, the surface charge density of the NRs decreases and the NRs are brought to the interface. The reduction in the interfacial energy at the water/oil interface upon the reduction of the dielectric constant of water is the driving force for this entrapment of the NRs. The thickness-dependent SERS activity of the resultant films (when molecules adsorbed on these NR films) has been investigated, and it was found that NR films have an order of magnitude stronger SERS enhancement compared to nanosphere films under similar experimental conditions [9.327].

Gold Nanorod Assembly by Surface Anchored Crown Ethers

Surface anchored crown ethers (end-functionalized) on GNRs were used to induce assembly of GNRs where the addition of specific metal ions resulted

in the assembly formation. The approach was reported by Nakashima et al. [9.328]. They synthesized two thiol-modified crown ethers, 2-((6-mercaptohexyl)oxy)methyl-15-crown-5 (15-crown-5-SH) and 2-((6-mercaptohexyl)oxy)methyl-12-crown-4 (12-crown-4-SH) and the synthesized crown ethers were added to purified NR dispersions. Covalent attachment of these crown ethers onto the end faces of the NRs through the thiol moieties is possible. In the presence of metal ions corresponding to the anchored crown ethers, assembly of the GNRs resulted. The concentrations of crown ethers and cations added controlled the structure of the GNR aggregates assembled (side-to-side and end-to-end fashion). UV/Vis spectra demonstrated the corresponding changes and the intensity of the longitudinal absorption of the NRs gradually decreased, and the peak was initially red-shifted and then blue-shifted. Potassium ions (K^+) can form a 2 : 1 sandwich complex between the 15-crown-5 moiety, leading to assembly formation and resultant coupling of the plasmon absorbance, in turn leading to changes in the spectral features. This was used for specific detection of metal ions.

Gold Nanorod Assembly Induced by a Magnetic Field

Magnetic field-induced assembly of GNRs is possible by imparting magnetic characteristics to GNRs. For this, Pt-doped GNRs (Fig. 9.30a) were homogeneously coated with metallic Ni through hydrazine reduction in aqueous solutions. This resulted in a quasi-epitaxial growth of an Ni shell on the GNRs (Fig. 9.30b) [9.329]. Since Pt has a much higher redox potential, it will become reduced first compared to nickel. Upon reduction Pt forms small nuclei which act as a nucleation agent, on which Ni can be catalytically reduced. When the Ni-coated GNRs (Au@Ni NR) were allowed to dry on a TEM grid under the influence of an external magnetic field (0.2 T), the NRs became aligned in a chain-like structure in the direction of the applied field (Fig. 9.30c). However, the orientation of individual rods within the chains was not found to be the same and coexistence of both side-to-side and end-to-end assemblies was observed, pointing towards the complex magnetic response of the system [9.329].

Assembly of Various Anisotropic Nanostructures of Silver

Compared to gold, anisotropic silver NPs are more diverse. The main limitation in the case of Ag anisotropic particles is the difficulty to synthesize of them in

Fig. 9.30a–c Large area TEM of (a) GNRs after tip-coating with platinum and (b) nickel coated GNRs in the absence of magnetic field. Inset shows a high magnification image of a single Au@Ni NR and STEM-EDAX (STEM: scanning TEM) analysis of Au@Ni NRs, showing the relative distribution of the elements (Au = red; Ni = green). (c) Au@Ni NRs, dried on the TEM grid under an external magnetic field (0.2 T) (after [9.329])

a monodisperse fashion. The presence of a surfactant that caps the nanostructures formed and avoids their aggregation is common in all synthetic methodologies, and hence surfactant-induced assembly of these structures upon solvent evaporation is highly feasible. Jana et al. devised a seed-mediated growth approach for preparation of silver NRs with varied ARs [9.330]. The approach was very similar to that used for making GNRs. A spontaneous self-assembly process assisted by solvent evaporation was observed upon shape separation of these NRs, resulting in a 2-D smectic liquid-crystal-like superstructure (Fig. 9.31a,b). Recently, a new method to produce monodisperse size-controlled faceted pentagonal silver NRs by thermal regrowth of decahedral silver NPs using citrate as the reducing agent was reported by Pietrobon et al. [9.43]. The resultant structures were highly monodisperse and showed a great tendency to self-assemble into smectic mesophases such as densely packed rafts and 3-D arrays when the dispersions dried (Fig. 9.31c–h). It was also noted that the fivefold symmetry of the constituent NRs is always overridden by the long-range hexagonal order within the layers [9.43].

Fig. 9.31a–h TEM image of shape-separated (a) silver NRs self-assembled on TEM grids and (b) silver NWs. (c–f) SEM images of self-assembled packing of monodisperse faceted pentagonal rod AgNRs with different aspect ratio forming 3-D superlattices. (g, h) show the top view of the assembly ((a, b) after Jana et al. [9.330] and (c–f) after [9.43])

The Langmuir–Blodgett (LB) technique is one of the most widely used methods to assemble a large area monolayer of nanosystems. Nanowires (NWs) with ≈ 50 nm diameter and 2–3 μm length were assembled into a large area of about 20 cm^2 by Tao et al. using this approach (Fig. 9.32) [9.331]. First, the PVP capping of the as-prepared NWs was replaced with 1-hexadecanethiol ligands to make them hydrophobic.

These NWs were then redispersed in chloroform, followed by transferal onto a water surface of the LB trough and were then assembled by the LB method. Large area, side-by-side aligned NWs resembling the nematic 2-D ordering of a liquid crystal were obtained.

Fig. 9.32 (a,b) Photographs of LB NW assembly process at different compression stages. (c–f) SEM images (at different magnifications) of the silver NW monolayer deposited on a silicon wafer (after [9.333])

An alternating extinction pattern was exhibited by these aligned NW areas when the sample was rotated every 45° [9.331]. The same group, following a similar methodology, was able to create novel SL architectures composed of different polyhedral building blocks, including truncated cubes, cuboctahedra, and octahedra of Ag nanocrystals [9.332]. In the superstructures formed, the packing and the dimensions were determined by the choice of the nanocrystal building block. For example, truncated cubes formed a square lattice by assembling in a face-to-face manner. However, cuboctahedra (which are comparatively more truncated polyhedral particles) assembled to make a rhombohedral unit cell, formed by shearing of the square lattice [9.332].

Bae et al. recently reported the assembly of Ag nanoprisms (Fig. 9.33a,b) [9.334]. They were able to assemble the prisms with anisotropic orientation and studied the orientation-dependent properties of these assemblies [9.334]. Rycenga et al. reported an interesting strategy to assemble Ag nanocubes by selective functionalization of each face [9.332]. They prepared five distinct SAM-modified Ag nanocubes from the possible combinations of hydrophobic and hydrophilic faces and these were assembled into four different nano-

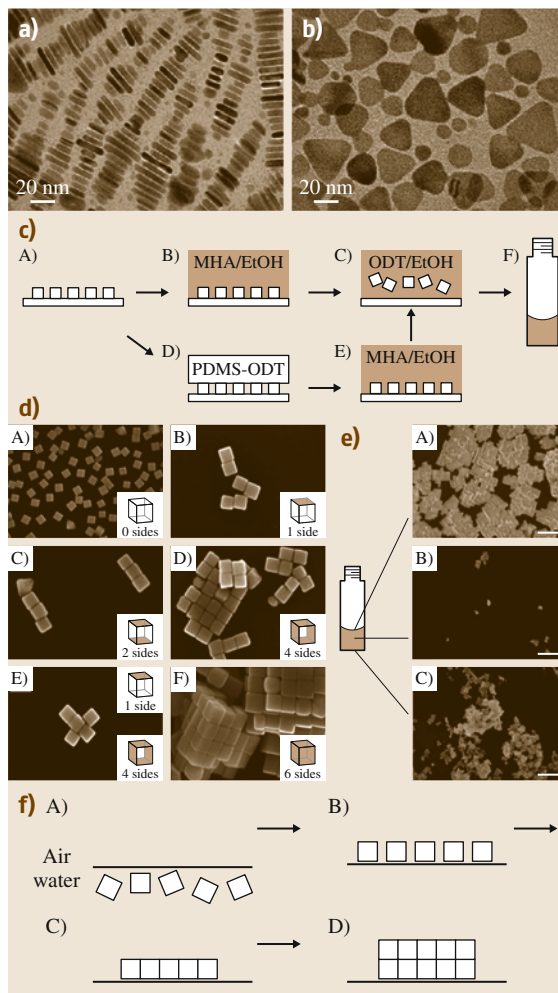

Fig. 9.33a–f TEM images of assembly A (a) and B (b) (after Bae et al. [9.332]). (c) A schematic representation of specific functionalization of Ag nanocube faces. (d) SEM images of Ag nanocubes and the assemblies depending upon the functionalization. (e) SEM images of ODT-functionalized Ag nanocubes sampled at different parts in a reaction vessel. (f) Schematics depicting the mechanism of formation of self-assembly at the air–water interfaces (after [9.332])

structures and one microstructure (Fig. 9.33c–f). The mechanism of the assembly was explained on the basis of hydrophobic interaction and solvation-free energy. Figure 9.33c depicts the methodology adopted for selective functionalization of the Ag cube faces. The selective functionalization was carried out by protecting the Ag nanocube, faces which are in direct contact with

a clean Si substrate, and the free faces were functionalized sequentially with solutions of alkanethiols, and polydimethylsiloxane (PDMS) inked with alkanethiols. Nanocubes that were not functionalized did not show any tendency to assemble. Single face functionalization of the nanocube with hydrophobic octadecanethiol (ODT), resulted in the formation of dimers, joined at the hydrophobic faces in order to try and move this face away from water. Nanocubes with two opposing faces functionalized with ODT formed linear chains.

When four faces of the nanocubes were functionalized with ODT, a sheet-like superstructure was obtained. Upon mixing Ag nanocubes with four hydrophobic faces and one hydrophobic face (1 : 4 ratio), star-shaped structures were obtained. When all six faces were functionalized, they formed 3-D SLs. Figure 9.33f schematically illustrates the self-assembly process of Ag nanocubes, completely functionalized with a hydrophobic SAM, at the air–water interface [9.332].

9.6 Functionalized Metal NPs

The adding of more functional capabilities and preparing functionalized nanomaterials has received considerable attention in the recent past. The main strategies for functionalization are ligand exchange reaction, using modified thiol as the capping agent in the Brust method or adding more components to the system such as making core–shell structures. In this section, various methods employed for the functionalization of monolayer-protected NPs and various approaches for the synthesis of functional core–shell particles are discussed. The presence of thiol end groups on the ligand have been utilized to anchor various photoactive molecules such as derivatives of porphyrenes [9.336], fullerenes [9.337], pyrenes [9.338], stilbenes [9.339], fluorenes [9.340], resorcinarenes [9.341], azobenzenes [9.342], etc., on the surface of GNPs.

GNPs having a double shell structure with the inner shell made of spiropyran have been used to control the photo-controlled binding and release of the outer shell of amino acids [9.343]. In the absence of light, spiropyran moieties exist as closed-rings (a nonpolar colorless form). Upon irradiation of light, spiropyran changes to the highly polar, colored merocyanine form. This mero-

cyanine (the open ring form) can complex with amino acids to form the second layer (Fig. 9.34). Thus, this system can be used for the light-mediated binding and release of amino acid derivatives.

In specific cases, the attachment of a fluorescent moiety onto the surface of NPs was found to alter the fluorescence intensity. For example, attachment of pyrenemethylamine on GNPs found to increase in the fluorescence of pyrene [9.343]. Generally, metals quench the fluorescence and the observed trend was different. This difference was explained as follows. The binding of nitrogen onto gold suppresses the electron transfer between the nitrogen and the pyrene ring (Fig. 9.35), which results in enhanced fluorescence.

9.6.1 Core–Shell Nanoparticles

Particles with a well-defined core and a shell (both in the nanometer regime) are called core–shell NPs. They have found applicability in diverse fields such as pharmaceuticals, chemical engineering, biology, optics, drug delivery, and many other related areas in addition to chemistry. Recent years have seen large efforts

Fig. 9.34 Reversible binding of amino acids with spiropyran-capped GNPs (MC: metal cluster) (after [9.335])

Fig. 9.35 Gold NP-assisted enhancement of fluorescence in pyrenemethylamine. Due to the attachment of nitrogen onto the NPs, conjugation between the lone pair on nitrogen and the pyrene ring is blocked. This is indicated by an arrow with a cross mark (after [9.343])

to develop core-shell colloidal NPs with tailored structural, optical, surface, and other properties [9.344, 345]. The formation of a protecting shell to the core imparts several functional attributes to these hybrid structures. They are:

1. Solubility and stability
2. Monodispersity in size
3. Ease of self-assembly
4. Core and shell processability
5. Applications in catalytic, magnetic, chemical, and biological fields, as well as in nanoscale electronics and optics.

A brief description of the diversity of core-shell systems involving noble metals is presented below.

Metal-Metal Oxide Core-Shell NPs

The scientific community has shown tremendous interest in this category of NPs, and these are among the most widely studied core-shell nanosystems. As discussed in an earlier section, the intense color exhibited by metallic NPs can be varied by controlling the size of these NPs. However, the chance of aggregation is a major problem associated with their handling. Making core-shell structures is one of most efficient ways to overcome this difficulty. Various strategies such as coating with silica [9.346], titania [9.347], zirconia [9.348], and maghemite [9.349] have been reported in this direction. A procedure to prepare silica-coated nanosized metal NPs was reported by Liz-Marzán et al.. This procedure is applicable for various metals such as Au, Ag, and CdS [9.350]. The approach involves the use of 3-aminopropyltrimethoxysilane (APS), the silane coupling agent, which can bind to the NP surface. This also

Fig. 9.36a-d TEM images of silica-coated GNPs. The shell thicknesses are (a) 10 nm, (b) 23 nm, (c) 58 nm, and (d) 83 nm (after [9.344])

acts as an anchor point for chemical deposition of silica (SiO_3^{2-}).

In this method, the shell thickness of the silica can be controlled (from 10–83 nm) and according to the thickness, the absorption characteristics are also tunable [9.344]. TEM images of Au@SiO₂ NPs with different shell thicknesses synthesized using the above method are shown in Fig. 9.36. Methodologies for the creation of various other inorganic coatings such as zirconia, yttrium basic carbonate, titania, titanium nitride, and Fe₂O₃ are available in the literature. Factors such as the size and shape of the core particles and the relative ratios of the reactants can control the thickness of the shell. Liz-Marzán et al. prepared TiO₂-coated Ag NPs by simultaneous reduction of Ag⁺ and condensation of titanium butoxide [9.347]. As an extension to this methodology, ZrO₂- and TiO₂-coated Au and Ag NPs were prepared later [9.348].

A single-pot method for the synthesis of Pt-maghemite (Fe₂O₃) core-shell NPs where the reduction of platinum acetylacetonate in octyl ether produces Pt NPs and subsequent thermal decomposition of iron pentacarbonyl creates layers of iron oxide on the surface was reported recently [9.349]. The complexation of a negatively charged titanium(IV) bis(ammonium lactate) dihydroxide with poly(dimethyldiallylammonium hydroxide) was used for coating Au NPs with titania by Mayya et al. [9.351].

Fig. 9.37 HRTEM images of Ag@ZrO₂ core-shell NPs functionalized with a stearate monolayer (after [9.352])

Reverse micelle and sol-gel techniques are also employed for synthesis of metal-metal oxide core-shell NPs. The inorganic coatings around the NPs modify the optical properties of the systems in addition to stabilizing them against coalescence. The core-shell geometry also allows shell functionalization using appropriate organic monolayers [9.352] for better redispersibility and ease of handling. High-resolution TEM images of a stearate-functionalized Ag@ZrO₂ core-shell NP are shown in Fig. 9.37. Although the organic monolayer build-up around the ZrO₂ shell is not clearly seen, the distinct core-shell geometry is visible from the image.

A special approach to synthesize Au@SiO₂ core-shell NPs by incorporating a mercaptosilane at the core-shell interface was devised by *Chen and Katz*, who exploited the strong interaction between thiols and gold [9.353]. They achieved the highest degree of functional group organization at the core-shell interface. Recently, Wang et al. synthesized Au-SiO₂ inverse opals by colloidal crystal templating.

Bimetallic Core-Shell NPs

Due to the high demand for catalysis, a large number of bimetallic core-shell NPs has been synthesized lately. Some important examples are the synthesis of Au-Pt core-shell alloys by the simultaneous reduction of chloroauric acid and chloroplatinic acid by *Henglein* [9.117], a single-step procedure for the synthesis of Au-Pt core-shell NPs by *Yonezawa and Toshima* [9.354], the synthesis of Au core-Pt shell NPs by simultaneous reduction of PtCl₆²⁻ in aqueous gold sol by *Schmid* et al. [9.355], etc. The synthesis of a variety of bimetallic systems including Ag/Cd, Ag/Pb, and Ag/In by a γ -irradiation-based approach was reported as early as 1980 by *Henglein* [9.117]. Synthesis of Ag-Au core-shell NPs by *Mulvaney* et al. [9.356] and *Link* et al. (NPs of 17–25 nm size) are also available in the literature [9.357]. *Kim* et al. synthesized Au-Ag core-shell NPs and studied their optical characteristics

such as linear extinction and resonant hyper-Rayleigh scattering [9.358].

The optical behavior and stability of Ag core-Co shell NPs was studied by *Sobal* et al. They showed that the core-shell particles exhibit an optical behavior distinct from the individual components, and the presence of a noble metal also protects the Co shell against oxidation [9.359]. *Cai* et al. developed a low-temperature synthetic protocol for Cu@Au core-shell NPs [9.360]. The formation of core-shell alloy NPs resulted in a good voltammetric response of Cu, which was utilized for electrochemical DNA hybridization detection assays. The oxidative peak current of the Cu colloid is much higher than that of Au of the same size and quantity. The coating of a layer of Au on the Cu core helped to protect the Cu from oxidative degradation and can also provide an active surface for immobilization of oligonucleotides. The synthesis of dumbbell-shaped Au-Ag core-shell NRs by seed-mediated growth under alkaline conditions was reported by *Huang and Matijevic* [9.361]. This method uses GNRs as seeds in the presence of Ag and ascorbate ions. Ag ions that are reduced by ascorbate are deposited on the surface of the Au NRs to form dumbbell-shaped Au-Ag core-shell NRs. Recently, the synthesis of Au-Ag core-shell NPs using tyrosine as a pH-dependent reducing agent was reported by *Sastry* et al. [9.362].

Semiconductor Core-Shell NPs

Similarly to metallic NPs, semiconductor nanocrystals also exhibit interesting size-dependent optical properties (fluorescence) due to the confinement of electronic wave functions. However, in order to obtain highly luminescent nanocrystals, their surface must be precisely controlled. The presence of a large number of surface defects (e.g., nonstoichiometry, unsaturated bonds, etc.) can have a large impact on their luminescence. Core-shell-type semiconductor NPs or quantum dots demonstrate novel properties that make them attractive for various applications. The photoluminescence quantum

yield can be increased by covering the nanocrystallites with higher-band-gap inorganic material, which passivates the surface nonradiative recombination sites. Moreover, compared to their organic analogs, NPs covered with inorganic composite materials are much sturdier and more stable. Yang et al. reported the off-resonance optical nonlinearities of Au@CdS core-shell NPs, embedded in BaTiO₃ thin films [9.363]. Due to their large third-order nonlinearities and ultrafast nonlinear optical response, semiconductor NPs are attracting a great deal of attention.

Polymer-Coated Core-Shell NPs

Polymer-coated core-shell NPs have found application possibilities in diverse fields ranging from catalysis to industry where these NPs are used in making additives, paints, and pigments, etc. There are mainly two classes of synthetic methodologies for polymer capping of NPs, namely: (a) polymerization at the NP surface, and (b) adsorption of preformed polymer onto the NP cores. The most common methods used for the preparation of polymer core-shell structures are:

1. Monomer adsorption onto NPs followed by polymerization [9.360, 365–367]
2. Heterocoagulation polymerization [9.364]
3. Emulsion polymerization [9.368, 369].

The colloidal particles themselves or an external initiator added to the reaction mixture can catalyze the polymerization. Using a pretreatment method, Huang and Matijevic [9.361] reported the synthesis of polydivinylbenzene coated silica particles. Following a similar strategy, polydivinylbenzene-poly(vinylbenzyl chloride) copolymers, poly(vinylbenzyl chloride), and double shells of polydivinylbenzene and poly(vinylbenzyl chloride) were also synthesized. In specific cases, where cores consist of dyes, polymer coating of the particles allowed the dyes to be retained inside the nanocores because the polymer shells are permeable only to small inorganic ions and not to big dye molecules. As was mentioned before, polymerization can also take place in the presence of catalytically active cores.

Several factors affect the thickness of the polymer coating: the contact time with the core, the type of core employed, and the nature of the polymer [9.360]. Feldheim et al. reported an excellent strategy for the synthesis of polymer-coated NPs [9.364] where the particles in the pores of a membrane were trapped

Fig. 9.38a,b TEM of polypyrrole-capped Au NPs (a) and with further increase in shell thickness by polymerization with poly(*N*-methylpyrrole) (b) (after [9.364])

and aligned by vacuum filtration. Then, inside the pore, the monomers were polymerized. Through this method, polypyrrole coated Au NPs can be prepared; corresponding TEM images are shown in Fig. 9.38. Figure 9.38b illustrates the increased shell thickness as a result of the change in the monomer for the polymer shell. Hence, this methodology allows control of the thickness and composition of the polymer coating. Generally for most of these polymerization reactions, the thickness of the coating depends on the polymerization time. Heterocoagulation of small particles with larger ones assisted with heating is another widely used method for preparing polymer coating. Through this method, polystyrene cores coated with a uniform layer of polybutylmethacrylate have been prepared.

The third technique, emulsion polymerization, has been widely employed for the synthesis of polymer-capped core-shell NPs. The important feature of this approach is that NPs of different size regime (from sub-nanometer to micrometer-sized organic and inorganic particles) can be coated with polymer. Polymerization of styrene and/or methacrylic acid in emulsions of oleic acid resulted in the formation of a uniform polymer layer around the metal core. Compared to uncoated particles, the polymer-coated particles are highly etch-resistant and can be easily centrifuged and redispersed. These NPs can be made in the form of thin films through the use of self-assembly techniques. The layer-by-layer (LbL) templating strategy is commonly used for this. Here, a polymer solution (having an opposite charge to that on the particles) in excess of that required for saturation adsorption is added to the colloidal dispersion. The polymer adsorbs onto the NPs through electrostatic interactions.

9.7 Applications of Gold and Silver Nanoparticles

The unique properties exhibited by gold and silver NPs such as SPR, SERS, nonlinear optical properties, quantized charging effect, etc., have been utilized for a variety of applications in the areas of bio-labeling, bioimaging, sensors, catalysis, nanodevices, nanoelectronics, etc. [9.1, 154, 370, 371]. Although noble metal NPs have a long history as materials for many therapeutic applications, the advancements in the area of nanochemistry have broadened their potential in various biomedical applications. Apart from their biocompatibility, unique properties, and ease of functionalization with various biological molecules, noble metal NPs have been used for targeting and delivery of therapeutic doses of drugs to cancer cells. The large extinction cross-sections and tunable optical absorption of NPs such as NRs, NTs, nanocages, etc., in the NIR region (a wavelength region where blood and tissues are relatively transparent to radiation) make them good candidates for diagnosis and many other medical applications. The strong SPR of metal NPs enables imaging of individual particle locations with the use of various optical microscopic techniques such as dark-field optical and two-photon luminescence (TPL) microscopy [9.372]. GNRs and nanocages are ideal candidates for cancer cell imaging due to their tunable SPR peaks and scattering in the near infrared. The usefulness of gold nanocages as optical contrast agents has been demonstrated by optical coherence tomography (OCT) imaging [9.144]. They are the perfect raw material for robust and rapid diagnostic testing for many diseases. Living cells are highly sensitive to temperature, and increases of a few degrees can lead to cell death. NIR absorption and related photothermal effect are other important features of anisotropic GNPs [9.144, 370]. Compared with other nonmetallic photothermal absorbers, GNPs enable dual imaging/therapy functions. It has been demonstrated that several anisotropic nanomaterials such as NRs, NTs, nanocages, nanoshells, nanostars, etc., can be used for photothermal therapy [9.144, 370].

Gold and silver NPs have been found to be useful for optical limiting applications as well. Optical limiters have found applicability in fields including sensor and eye protection, optical communications, and optical information processing. Optical bistable materials are useful for functions such as logic gating and pattern recognition in optical computers. The applicability of Au, Ag, and Au-Ag alloy nanosystems for optical limiting applications was investigated in 2000 [9.373].

Initially, octanethiol and octadecanethiol-protected Au, Ag, and Au-Ag alloy NPs were synthesized, and optical nonlinearity was induced by 35 ps pulses at 532 nm. The samples were investigated using the Z-scan technique. It was found that they behaved either as saturable absorbers or reverse saturable absorbers, depending on the intensity of excitation. It was also found that Au and Ag NPs show nearly the same efficiency for optical limiting; however, the alloy clusters were found to be less efficient in limiting and were less photostable. An explanation based on the electron dynamics of the excited-state species was given for the behavior observed [9.373].

Gold and silver NPs have attracted considerable attention due to their high SERS [9.217, 374] activity, thus possessing strong advantages for the detection of molecules. They have been found to be useful for many applications in trace analysis of pesticides, biomolecules, bacteria, viruses, specific antigens, glucose, DNA, explosive materials, etc. [9.375]. Recently, it has been found that silica-coated GNPs can enhance the sensitivity of this method, and even detection of adsorbed hydrogen is possible with such materials [9.376]. Single-molecule detection is possible using SERS, and several protein and nucleic acid biosensors have been designed using this property of GNPs [9.375].

The properties of GNPs such as intense SPR and scattering of visible light have also been used for sensing applications. A variety of schemes based on the LSPR of GNPs have been developed for sensing organic vapors [9.377]. A composite material made of GNPs with pH-sensitive polymers has been used in a variety of pH-sensing schemes. GNP-based technologies are showing great promise in providing solutions to a number of environmentally important issues. They are highly promising for sensing and removal of heavy metal ions from water [9.378]. GNP-based colorimetric sensors have been widely used in this direction, overcoming some of the limitations of conventional methods because these assays do not use organic solvents, light-sensitive dye molecules, or sophisticated instrumentation. GNRs are capable of quick and selective sensing of mercury in tap water samples at the ppt level [9.379]. The selectivity and sensitivity towards mercury are due to the amalgamation of mercury and gold. Complete removal of mercury from water can be done by using GNPs supported on alumina [9.380].

Catalysis by active oxide-supported gold, silver, platinum, and palladium NPs is an ever-expanding area,

and a large number of new catalytic systems for various reactions have been widely exploited for many applications. GNPs can oxidize highly toxic CO to far less toxic carbon dioxide [9.222,380]. More recent investigations have shown that GNPs adsorbed and dispersed on an oxide support can be used as an efficient catalyst for hydrogenation of unsaturated substrates [9.1]. Thus, shape and crystal structure differences can lead to different catalytic rates [9.381]. In homogeneous catalysis, Narayanan and El-Sayed demonstrated that shapes with more corners and edge atoms have higher reactivity than similar NPs with fewer corner and edge atoms [9.382]. Catalytically active bimetallic gold-palladium NPs proved to degrade organic pesticides effectively [9.383]. GNPs are also used in solar cells to improve the efficiency, as the GNPs enhance the optical absorption in the range of visible light [9.1]. It has been recognized that NIR absorbing films made from GNPs can be used as an alternative to reflective coatings for blocking infrared (IR) radiation. NP-based approaches are highly desirable, being more economically viable than other methods. Certain nanomaterials have been used for the development of IR filters. Using a prototypical device, Pradeep and Sajanlal have demonstrated that the NIR-IR absorption exhibited by gold MFs can absorb a significant amount of heat, thereby reducing the temperature rise in an enclosure exposed to daylight [9.160]. A few of these application possibilities are described in detail in the following section.

9.7.1 Water Purification

Among all these application possibilities, water purification remains one of the most important fields of application for any material. Noble metal NPs have also found tremendous possibilities in this arena as well. A specific review on this topic was discussed by the author in recent work, where a description about the important events during last 200 years in the area of drinking water purification was presented [9.23]. This section gives an overview about the use of noble metal NPs for the removal and detection of severely toxic contaminants including pesticides, halogenated organics, heavy metals, and microorganisms found in drinking water.

Degradation and/or Removal of Pesticides with Noble Metal NPs

The chemistry of noble metals (even in bulk form) for catalytic synthesis of organic compounds is well documented. However, their reactivity with halogenated

hydrocarbons was not explored until recently. The first example for a metal (here, a transition metal) interacting with halogenated organics was initiated following the discovery that zero-valent iron catalyzed degradation of halogenated aliphatics [9.384]. Similarly, there were attempts to study the degradation of halocarbons [9.385] by using other reactive metals such as magnesium, tin, and zinc. However, until 1998, noble metals were never thought to be attacked by halocarbons. Noble metals had very low reactivity. However, later investigations revealed that in colloidal state noble metals are reactive. It was postulated in early 1998, based on absorption studies of silver colloid with oxygen and carbon tetrachloride, that carbon tetrachloride induces oxidation of silver colloid in a manner similar to oxygen [9.386]. Another study concluded that the degradation of noble metal clusters can be done by chlorine radicals produced by UV irradiation of halogenated organics [9.387]. It was also suggested that many organosulfur compounds adsorb on noble metal NP surfaces [9.388] and carbon disulfide undergoes dissociation on silver surfaces.

In early 2003, the first detailed report, from the authors' group, appeared on the interaction of noble metal NPs with halocarbons [9.389]. In a manner strikingly similar to the reaction of other metals with halocarbons, nanoscale noble metals also react with halocarbons. Through reductive dehalogenation, the reaction leads to the formation of metal halide. An important thing to be noted is the formation of amorphous carbon in this process [9.389], and harmful that the reaction proceeds efficiently at room temperature [9.389]. The reaction of noble metal NPs with halocarbons could be considered as a classic example of the particle size-based reactivity of metals [9.389] as noble metals in bulk form are not attacked by halocarbons.

Using a number of spectroscopic techniques, this reaction was studied to understand the reaction mechanism [9.389]. It was observed that plasmon intensity in the absorption spectrum gradually decreases without any shift in the plasmon peak position. When the reaction product obtained at the end of the reaction was analyzed using x-ray diffraction (XRD), features were similar to AgCl. Thus the conversion of metal to metal halide was confirmed. In the Raman spectra, broad G and D-band signatures of the amorphous carbon centered at 1550 and 1288 cm^{-1} was seen, pointing towards the formation of amorphous carbon.

Gas chromatographic and IR spectroscopic measurements also confirmed the complete mineralization of the halocarbon, as there were no reaction prod-

ucts. A reaction mechanism was suggested that depends on the spectroscopic observations [9.389]. We can represent the reductive dehalogenation of carbon tetrachloride as

We can also consider the reaction from an electrochemical standpoint as

The excess surface energy of the NPs is the reason behind the reaction proceeding at the nanodimension. This is very helpful in overcoming the thermochemical barrier and the reductive dehalogenation reaction is exothermic [9.389]. After understanding the mineralization of halocarbons, the research was extended to the field of pesticides. They are another important family of halogenated organics. Pesticides such as endosulfan [9.390] and chlorpyrifos [9.391,392] belong to halogenated organic family, and malathion [9.391,392] is an organophosphate type pesticide.

When the pesticides interacted with gold and silver NPs, their spectroscopic behaviors were different. A decrease in plasmonic absorption intensity was observed when endosulfan reacted on gold. There was the emergence of an additional peak at higher wavelengths as well [9.393]. This was due to adsorbate binding onto the NP surface, thereby leading to particle aggregation. IR measurement on the residue obtained after the adsorption process showed a substantially broadened signature of the pesticide. There were significant changes in the feature at 1192 cm^{-1} (Si=O bond) and negligible changes in the feature at 750 cm^{-1} . This indicated that the interaction largely occurs through the sulfur. The reverse was the case with endosulfan and silver. The plasmon absorption did not change significantly in the case of endosulfan on silver surfaces. The IR spectrum of the residue obtained after the reaction was analyzed and the adsorption of endosulfan onto silver surface was confirmed.

The heterogeneous adsorption of pesticides onto NP surfaces was one of the major aspects of the reaction chemistry [9.391]. For removal of pesticides from solution, noble metal NPs supported on alumina were

found to be very effective. When the input concentration was 50 ppb, using alumina-supported noble metal NPs, pesticides could be completely removed from the aqueous phase. The complete removal was confirmed using gas chromatography, which did not show any significant signature of pesticides [9.391]. It is very clear that the chemistry of supported noble metal NPs can comfortably be utilized for the complete removal of most of the pesticides from drinking water whether they are organochlorine (e.g., simazine, lindane, atrazine, etc.) or organosulfur pesticides (e.g., triazophos, quinalphos, etc.), or contain nitrogen-based functional groups (e.g., carbaryl, carbofuran, monocrotophos, etc.). This versatility of noble metal NPs in removing a wide variety of pesticides makes them an attractive candidate for drinking water purification. The strong attachment of NPs on substrates such as alumina can ensure the stability of the supported hybrid structures and can ensure that the NPs will not be released into water under the conditions used in water purifiers.

Detection of Pesticides in Drinking Water with Noble Metal NPs

Ultralow concentration sensing of pesticides in drinking water is as important as it is to remove these toxic pesticides. A large number of water resources across the world are becoming severely polluted by the widespread, large-scale use of different pesticides. Hence, it is imperative to develop rapid, sensitive, and selective detection protocols for detecting such molecules [9.394,395]. Several protocols have been put forward for ultralow-concentration detection of pesticides during the past 25 years [9.396]. Methods such as chromatography, mass spectrometry, and biosensors are some of most practiced methods for this and they offer high sensitivity and selectivity. However, the high sophistication, amount of time required to evaluate the data are the main limitations when considered for common use.

Nanomaterials are expected to contribute in this area as well by developing rapid and facile measurement methods based on nanomaterial chemistry [9.397]. Oligonucleotide-modified GNPs are being used for the biomolecular colorimetric detection of polynucleotides at ultralow concentrations [9.306]. Unlike materials chosen as adsorbents where a higher surface area is a prerequisite, the substrate used for contaminant detection should produce a large change in the surface with adsorbate interaction and a consequent manifestation in reliable spectroscopic signatures. Another important aspect about contaminant detection is the se-

lectivity. This can be ensured by choosing appropriate nanomaterials and functionalizing them with suitable ligands. A good example regarding selective detection of cysteine and glutathione at micromolar concentrations using GNR is described in more detail in another section (Sect. 9.5.2) [9.306].

Two general strategies have been employed for the ultralow-concentration detection of pesticides using GNPs:

1. Variation in the principal properties of a functional group attached to the noble metal NP surface in the presence of organic molecules. This approach has not yet been utilized for the detection of pesticides in drinking water. However, the nature of the molecules detected being similar, this technique can be modified for detection of pesticides as well. Europium ions (Eu^{3+}) when anchored on the surface of a GNP are known to show enhanced fluorescence intensity [9.398, 399]. The interaction of organophosphorus molecules with this will result in the fluorescence being quenched. Organophosphorus molecules tend to bind with GNPs, resulting in the release of Eu^{3+} ions. In another study, a zirconium–phosphate-terminated surface was fabricated by treating GNPs supported on silica gel with zirconium (Zr^{4+}) and POCl_3 [9.400, 401]. This surface demonstrated a strong affinity towards organophosphorus compounds. The resultant interaction induced visible changes in the optical properties of the GNPs. In another approach, paraoxon was detected using GNPs functionalized with an antibody specific to paraoxon [9.402]. The electrochemical properties of the system were modified upon interaction with paraoxon. Low concentrations (at ppb level) were detected in this method. Using a metalloenzyme, organophosphorus hydrolase (OPH), which can hydrolyze a large variety of organophosphate pesticides and neurotoxins, an ultralow-concentration detection strategy was devised recently [9.403]. GNPs were functionalized with OPH enzyme. Later fluorophore molecules were positioned at the OPH active sites. These fluorophore molecules were released upon addition of organophosphorus compounds, resulting in changes in the fluorescence intensity. Enzyme-mediated hydrolysis of acetylthiocholine can generate species with reducing capabilities, and Au NPs can be synthesized using this [9.404]. The presence of toxic organic molecules can hinder the catalytic activity of the enzyme, acetylcholine esterase (AChE).

This inhibition of the enzyme can result in quenching Au NP production due to the unavailability of the reducing agent. This quenching can even be effected by nanomolar concentrations of toxic organic molecules. The resultant changes are manifested in the optical properties of the GNPs. A similar reaction will result in changes in electrochemical currents as well. Au NPs functionalized with AChE were used to hydrolysis acetylthiocholine, and the reaction was utilized as a pesticide sensor through measurement of the electrochemical current, which depends on the extent of formation of thiocholine in the presence of pesticides [9.405]. A summary of efforts related to the use of biomolecular immobilized Au NPs for electrochemical sensing can be found in a recent review article [9.406]. The enzyme is known to catalyze conversion of acetylcholine chloride in the following way [9.407]:

As discussed above, the presence of organophosphorus pesticide molecules inhibit the activity of AChE to hydrolyze Ach. An attenuation of light when AChE is covalently bound onto GNP surfaces which can be correlated with the pesticide concentration manifests this inhibition [9.408]. The dephosphorylation by 2-pyridine-aldoxime methiodide (2-PAM) can reactivate AChE. Thus the sensor can be reused for many operations. Detection of pesticides in the ppb limit is possible by this method. A correlation between the shift in plasmon wavelength of Ag NPs and the pesticide concentration was also used to detect pesticides [9.409]. Indoxyl, a product of the reaction of certain organophosphorus compounds and indole is fluorescent in nature. Indole anchored on the Au NP surface was reacted with organophosphorus pesticides and the fluorescence (resulting from the indoxyl formation) was utilized for the pesticide detection [9.410]. A ppt level detection was reported by this method.

2. Interaction with pesticides results in changes in the optical properties of noble metal NPs. Chemistry at the nanolevel is extremely sensitive. Hence, even at ultralow concentrations, the interaction between pesticides and NPs brings about considerable changes in properties. The interaction of an endosulfan–noble metal NP system can be followed spectroscopically by using different techniques such as the UV/Vis absorption spectrum, the Fourier

transform IR (FTIR) spectrum, etc., which use the changes in the signatures of the NPs to detect the presence of pesticide on NP surfaces. One of the easiest ways is to observe sensitive color changes of the solution [9.393]. Colorimetric methods are simple, user-friendly, and comparatively less sophisticated. Moreover, the intensity of the color change is nearly quantitative. Reports suggest that the colorimetric detection of pesticides at a concentration level of 1 ppm (this is more than 100 times the permissible levels) is possible. To take nanochemistry-based methods to the levels relevant to drinking water, different strategies have been employed. One of the most established approaches is salt-induced aggregation of noble metal NPs in the presence of pesticide [9.411, 412]. Studies showed exceptional colorimetric changes due to pesticides at low concentrations in a salt-induced aggregation method, which can be easily followed by absorption measurements. A recent study indicated that chlorpyrifos induces severe aggregation to GNP- Na_2SO_4 solution, and this results in the change in the solution color and thus absorption characteristics [9.411]. Figure 9.39a shows the UV/Vis spectral changes and the corresponding color changes. The fast response time and simplicity of the method points to the on-field adaptability of the process [9.411]. A change in the SPR band position and the intensity of humic acid-protected silver NPs were utilized for detection of herbicides. However, these changes were observed only at high concentrations of herbicides [9.413].

In addition to the above-mentioned two general approaches, the enhancement of Raman signals in the presence of noble metal NPs has been extensively utilized for detection of organic molecules. A dye molecule, rhodamine 6G, where very low concentration (equal to single rhodamine 6G molecule) detection through an SERS-based method is the most studied example [9.414–417]. Recent investigations indicated higher Raman signal enhancements in the presence of anisotropic gold and silver nanostructures, which can lead to the detection of ultralow concentrations of organic molecules [9.418, 419]. Using the Langmuir–Blodgett assembly of anisotropic nanostructures, the detection limit can be further improved [9.331]. This is discussed in more detail in another section (Sect. 9.7.6). Molecular level details about the interaction between proteins and DNA interactions were studied using this method recently [9.420]. Another study revealed the

feasibility of using humic acid-protected GNPs for the detection of organic contaminants [9.421]. The high affinity of humic acid (HA) towards a variety of organic molecules and the low background SERS spectrum of HA (the spectrum is relatively weak in absolute intensity) also helps in the detection process.

Chemistry of Heavy Metal Ions with Noble Metal NPs

Sequestration of heavy metals is considered to be one of the most interesting application areas of noble metal NPs in drinking water purification. The pioneering studies regarding the interaction of metal ions with noble metal NPs were carried out in the early 1990s [9.386] and indicated that many of the previously known properties of metals do not hold true as the size goes down to the nanometer regime.

As the size of the particle increases, the redox potential of a microelectrode becomes more positive

For a free silver atom ($n = 1$), the reduction potential is -1.8 V. However when $n \rightarrow \infty$ (for conventional silver electrodes) the potential reaches a value of 0.799 V [9.422]. Such drastic size-dependent changes in electrochemical properties will have high impact in the interaction of these NPs with pesticides and heavy metals in water. The conversion of Ag clusters into colloidal metal particles catalyzed by Cu^{2+} illustrates this effect. The reaction follows the following scheme [9.423]

followed by similar reaction of Ag_{n-1} ,

Here, the cluster containing n atoms is depicted as Ag_n , and Ag_{n+m} correspond to a colloidal particle composed of $n + m$ atoms. Aggregation of unstable clusters results in the formation of colloidal particles. The reaction becomes feasible due to the rather negative potential of silver clusters. The reaction can be followed by the disappearance of the absorption feature of clusters and an increase in the intensity of the 380 nm band of metallic silver. A similar study on the interaction of Cd^{2+} with 4 nm colloidal silver particles is also available [9.424]. In this reaction, 1-hydroxyethylmethyl radicals generated radiolytically in a mixed solvent system (acetone + 2-propanol) results in the production of colloidal cadmium via electron transfer. An absorption feature corresponding to colloidal cadmium starts to appear around 250 – 280 nm, confirming this reduction. A concurrent red-shift was observed for the silver plasmon band (375 – 383 nm). Another study about the interaction between Ag NPs (0.25 mM in water) with Cd^{2+} solution (0.02 mM) reported the appearance of a separate absorption feature around the 550 – 600 nm region [9.425]. It is worth noting that in both studies, the size of the silver NPs remained constant. However, different spectral observations were made in the two methods. One method did not show any change after the addition of metal ions, while the other showed an instantaneous appearance of a new feature. Similar observations were seen in the case of other metal ions as well.

Several adsorbent systems including activated carbon [9.426], polyethyleneimine-modified cellulose [9.427], functionalized membranes [9.428], silica [9.429], and graphene [9.430] have been employed

for the removal of mercury from drinking water. All good adsorbents should have an extremely high metal adsorption capacity, minimum contamination of the water (e.g., minimum ion exchange), zero desorption under environmental conditions, and economic adaptability.

During the sequestration of heavy metals from drinking water by NPs, the adsorption chemistry plays an important role. Depending on the phase stability two metals can exist as an alloy with varying compositions. For example, gold and mercury can exist as Au_3Hg , AuHg , and AuHg_3 . Therefore, for 1 g of Au, a maximum adsorption of 3.05 g of Hg is possible. Hence, utilizing the alloy formation, a high efficiency adsorption process can be devised. Zero-valent iron was the first system where metal alloying induced sequestration of heavy metals was reported [9.431]. However, surface corrosion can reduce the capacity of iron to alloy with heavy metals. The use of noble metal NPs for this concept pointed towards the large possibility of these NPs in water purification [9.380]. An increased adsorption capacity of 4.065 g/g of gold is reported when mercury was reduced to the zero-valent state followed by alloying with GNPs. The mechanism of the reaction was studied using various techniques. Microscopic images demonstrated an increase in the size of the NPs upon addition of Hg. An amorphous layer of mercury was also observed around the NPs. In the absorption spectrum, a shift in the plasmon position along with a significant modification in the peak shape was observed (Fig. 9.38b). An X-ray diffractogram confirmed the formation of an alloy Au_3Hg phase. Quantitatively 738 mg gold can be used to decontaminate 3500 l of 1 ppm mercury [9.380].

Silver NPs have enhanced ability to function as a reducing agent for mercury and can exist with mercury in different phases as an alloy as well. Surface plasmon of Ag NPs experiences a blue-shift along with a decrease in intensity immediately upon introduction of Hg^{2+} ions. The partial oxidation of Ag NPs to silver ions results in the decrease in plasmon intensity whereas the shift can be due to the incorporation of mercury into the silver NPs [9.432, 433]. Aqueous mercury NP solutions are reported to exhibit a plasmon absorption band below 300 nm [9.434]. Hg-Ag alloy NPs synthesized via simultaneous reduction with sodium borohydride showed a plasmon in the region of 300 – 400 nm [9.435].

Silver NPs (average size 60 – 80 nm) prepared by the Turkevich method (discussed earlier) are known to show a tremendous growth in size up to over 600 nm upon mercury incorporation. This was attributed to the

nucleation of reduced mercury on the silver surface. Energy-dispersive x-ray analysis confirmed the homogeneous distribution of mercury on the silver NPs. The edges of the particles had a slightly higher concentration of Hg compared to the center. The surface adsorbed mercury atoms might diffuse rapidly into the silver core, resulting in a very fast disappearance of the silver plasmon band. In order to understand this, the reaction needs to be analyzed thermodynamically. The reduction reaction is

According to the potential in bulk scale, this reaction is thermodynamically feasible. However, as discussed earlier, the conditions are different in the nanoregime. At atomic scale, the $\text{Ag}^+|\text{Ag}$ (atom) cell has a reduction potential of -1.80 V . Hence it is reasonable to think that the reduction potential of the silver NP is likely to be much less than 0.8 V , which creates a strong driving force for the galvanic reaction to occur. The difference in the reduction potential of silver NPs and in the bulk state can be understood from the Ag-HCl system [9.436]. Silver in bulk form will not react with HCl. However, silver NPs prepared by the sodium borohydride reduction method demonstrate an unusually high reactivity with HCl. The plasmon band of silver NPs vanishes after the addition of HCl, confirming the dissolution. A white residue obtained after the reaction of silver NPs with HCl (AgCl) confirmed this.

This result can also be understood from the reaction

Hence, with bulk silver, there is no driving force for the reaction. However, at the nanoscale, the feasibility of the reaction points to the continuous increase of the reducing nature of the silver as the size reaches the nanoregime. Utilizing the ability of silver NPs to reduce a number of heavy metals, a variety of alloy NPs (e.g., Ag-Hg bimetallic NPs) have been prepared. Similarly Pd-Ag and Pt-Ag NPs [9.437] have also been synthesized using galvanic etching.

Recently, the authors' group has carried out extensive studies on the mechanism of Hg removal by silver NPs. A detailed study of the chemical interaction of heavy metal ions such as Hg(II), Hg(I), Pb(II), and Cd(II) with naked and protected silver

NPs was carried out [9.438]. Silver NPs protected by citrate (Ag@citrate, 30 nm average diameter) and MSA (Ag@MSA, 8 nm) were taken as the model nanosystems. With the help of various spectroscopic and microscopic techniques, it was concluded that the metal ions interact with both the core of the NPs and the functional groups of the capping agents, especially carboxylic acid functionalities (Fig. 9.40). It was also observed that both NPs studied were able to reduce Hg(II) and Hg(I) ions to metallic mercury, because of the feasibility of the redox reaction, and that no reduction occurred for Cd(II) and Pb(II). It was concluded that the reduction of Hg(I) and Hg(II) ions was by electrons supplied by the core silver atoms of the NPs at lower metal ion concentrations. At higher concentrations, the metal ions were chemically bonded to the carboxylate groups of the citrate and MSA, in turn, forming sulfides.

Using this same basic chemistry, a practical silver NP-based adsorbent for removal of Hg(II) from water was developed by the authors of this chapter [9.439]. The NPs were supported on alumina and its efficiency in removing Hg(II) from water was demonstrated. The study was also extended to novel noble metal nanosystems known as quantum clusters (discussed later in Sect. 9.8). The interaction of novel unsupported and supported MSA-protected clusters such as Ag_7 and Ag_8 with Hg(II), Cd(II), and Pb(II) in water at different concentrations was investigated [9.440]. It was understood that the interaction with these clusters is similar to that for corresponding larger NPs. It was concluded that Hg(II) was reduced to metallic mercury by both supported and unsupported clusters, due to the feasibility of the redox reaction discussed above, whereas no reduction happened for Cd(II) and Pb(II). This interaction resulted in the disappearance of the luminescence of the cluster, which may aid in sensing Hg(II). The metal ions were chemically bonded to the carboxylate groups of MSA at lower concentration, and due to this chemical affinity of the ligands and the lower silver content per cluster compared with the number of carboxylate groups, Hg(II) was not reduced at these lower concentrations.

Detection of Heavy Metals in Drinking Water with Noble Metal NPs

The maximum contamination limit (MCL) for various contaminants in drinking water was reviewed recently and MCLs for various contaminants were reduced. For example, the MCL for lead has been changed from 15 to 10 ppb and the MCL for arsenic has been revised from 50 to 10 ppb. Various methodologies for the detection

Fig. 9.40a–d X-ray photoelectron spectroscopy (XPS) spectra in the (a) C 1s, (b) O 1s, and (c) Ag 3d of Ag@citrate and Ag@MSA and (d) S 2p region of Ag@MSA. Traces (a) and (b) in (a–c) are due to Ag@citrate and Ag@MSA, respectively. From the authors' laboratory (after [9.439])

of mercury [9.441], arsenic [9.442], lead [9.443], and anions [9.444] are available. Similar to the methodology adopted for the detection of pesticides, there are two possible ways to detect metal ions by noble metal NPs.

Colorimetric Detection. Noble metal NPs can anchor various types of ligands on the surface and can intercede in several ligand-mediated reactions. Moreover, this anchoring or functionalization of metal surfaces generally results in sensitive changes in their optical properties [9.445]. Heavy metals can be detected using surface functionalized NPs [9.446]. Biomolecule-functionalized GNPs were used for this application recently. The interaction between metal ion and nucleotide, for example the Hg^{2+} -promoted formation of thymine–thymine base pairs [9.447, 448], was used for detection. Based on this interaction a scanometric device involving the use of an oligonucleotide chip array for the low concentration detection of metal ions was reported [9.449]. The aggregation of Au NPs functionalized with a DNA strand due to the hybridization action of enzymes in the presence of a substrate is another example of a similar approach [9.450–453]. The presence of specific metal ions can hinder the hybridization by catalytic cleavage of

the substrate. Hence upon addition of metal ions, the aggregates of GNPs become disengaged. This method has a detection limit of 100 ppb. Peptide-functionalized Au NPs were also utilized for colorimetric detection of Hg^{2+} and Pb^{2+} at the ppb level (distinct color changes for the two ions), via a similar methodology [9.454]. The peptide (Flg-A3 peptide with specific sequence, -Asp-Tyr-Lys-Asp-Asp-Lys-Pro-Ala-Tyr-Ser-Ser-Gly-Pro-Ala-Pro-Met-Pro-Pro-Phe-) was anchored on NP surfaces which also acted as the stabilizing agent due to its negative charge. The aromatic, charged, and hydroxyl groups in the peptide sequence distinguish heavy metal ions leading to plasmon shifts in the absorption spectrum-based nanomolar detection. Metal ion-induced assembly of GNPs in the presence of carboxylated peptide (tyrosine containing peptide $\text{NH}_2\text{-Leu-Aib-Tyr-OMe}$) was also used for the ppm level detection of various metal ions [9.455]. Simple colorimetric approaches based on the specific action of DNA enzymes towards metal ions (e.g., Cu^{2+} and Zn^{2+}) have also been also utilized for the targeted detection of metal ions [9.456, 457].

The mechanism of colorimetric detection usually depends on the complexation of ligands functionalized onto noble metal NP surfaces with specific metal ions. This results in observable optical changes at concentra-

tions in the ppm level. Various ligands such as gallic acid (Pb^{2+}), cysteine (Hg^{2+} , Cu^{2+}) [9.458], and mercaptoundecanoic acid (Pb^{2+} , Cd^{2+} , Hg^{2+}) [9.459] have been employed for this purpose.

The chemistry of metal NPs can also be utilized for the removal of heavy metals. The alloy formation between the metals gives rise to notable changes in the optical properties of noble metal NPs (as was discussed earlier) [9.379, 380]. Aggregation of Au NP surfaces modified by carboxylate groups can be induced by Hg^{2+} and pyridinedicarboxylic acid, leading to a colorimetric response [9.460, 461], fluorescence quenching [9.462], and enhancement of hyper-Rayleigh scattering intensity [9.463]. The selectivity of metal ions depends on the choice of carboxylate group. Generally, 3-mercaptopropionic acid [9.460, 461, 463], adenosine monophosphate [9.460], and mercaptoundecanoic acid [9.462] are used.

SERS-Based Detection. Utilizing the SERS activity of noble metal NPs, trace quantities of contaminants in drinking water can be detected. As was explained earlier (Sect. 9.4), the large electric field generation near the metal surface due to the collective oscillations of conduction electrons with the incident light leads to signal amplification. Charge transfer between the chemisorbed species and the metal surface leads to electronic transitions from the highest occupied molecular orbital (HOMO) to the lowest unoccupied molecular orbital (LUMO). Excellent reviews on SERS can be found in the literature [9.464]. Various attributes of SERS such as size-dependent SERS activity [9.415], single-molecule detection [9.416], and enhanced activity from assembled nanostructures [9.465] can be utilized for detection of contaminant molecules in drinking water. A recent study demonstrated the shape dependency of SERS-based concentration detection of arsenic in drinking water [9.466]. A detailed description of this is given in a later section (Sect. 9.7.6). Alterations in the conformation of DNA can inhibit their binding capacity to NP surface. This difference in binding capacity induced by Hg^{2+} on thymine-rich single-strand DNA tagged with a fluorescent dye was used for the detection of Hg^{2+} . NPs aggregated upon addition salt when DNA (which can prevent this aggregation) was not anchored on the surface leading to the detection [9.467]. It was also understood that Hg^{2+} can catalyze the formation of stable duplex DNA from single-strand DNA-functionalized GNPs through thymine- Hg^{2+} -thymine linkage [9.468]. This temperature-dependent process can be modulated by controlling the extent

of thymine-thymine mismatch. Surface modification of Au NPs with suitable molecules can result in enhanced metal ion capacity [9.469]. Raman vibrational modes are extremely sensitive towards the heavy metal coordination, which will become enhanced upon coupling with noble metal NPs.

Ultralow quantities of anions can be detected using SERS-based protocols. Perchlorate, thiocyanate, and cyanide ions have been detected using positively charged silver NPs protected by amino and amide groups which are immobilized on the silica surface [9.470].

Chemistry of Microorganisms with Noble Metal NPs

Silver, in zero-valent and ionic form, is known to possess antimicrobial effects [9.471–475]. As is illustrated in the historical perspective as well, it has been widely used as a common disinfectant for surgical masks [9.476], textile fibers [9.477], wound dressing [9.478], etc. Several scientific studies have been undertaken to understand the mechanism of this effect, and there exist a number of reviews regarding this [9.479–484]. Here, some important aspects of NP chemistry with microorganisms, that are relevant to drinking water purification are summarized.

Toxic effects of Ag NPs on a broad spectrum of microorganisms, including *Escherichia coli* [9.471, 474, 475, 484–486], *Pseudomonas aeruginosa* [9.484], *Vibrio cholera* [9.484], *Bacillus subtilis*, and the human immunodeficiency virus (HIV)-1 [9.487] are well documented. Before going into the mode of action of Ag NPs, it is important to understand the biocidal activity of silver ions. The precise mechanism behind the effect is not fully understood. However, protein inactivation and loss of replication ability of DNA are suggested as the route cause for this effect based on certain key observations:

1. When cells are subjected to external stimuli like heat, they will try to protect the DNA by forming a defense around the nucleus [9.488]. However, this defense mechanism cannot withstand certain external stimuli, which will result in denaturation of the DNA (loss of replication ability). When Ag ions were injected to *E. coli* and *Staphylococcus aureus*, a similar observation was made [9.489]. DNA condensation resulting from the formation of protective layers around the DNA was observed in this investigation [9.489]. A large-scale movement in the cellular components when encountering Ag ions

points to the capability of the cell to protect itself against external stimuli.

2. Studies indicated that the interaction of silver ions with the sulfur present in many proteins leads to protein inactivation [9.490]. It was also observed that external addition of sulfur-containing compounds led to neutralization of the antibacterial activity of silver. This confirmed the interaction between sulfur and silver.

The effectiveness of Ag ions is closely related to the nature of the charges on the cell surface (due to the presence of various functional groups) and the antibacterial composition. For example, if the antibacterial composition and charge on the cell surface are negative, the contact between these two entities will be minimal due to repulsion [9.491]. Silver can absorb oxygen in atomic form and this has been widely utilized for many organic reactions such as conversion of methanol to formaldehyde [9.492]. Also, bulk silver in water enriched with oxygen is known to oxidatively destroy microorganisms [9.493]. Cell viability is maintained by cellular membranes and in the case of gram-negative bacteria such as *E. coli*, the cellular permeability is controlled by a lipopolysaccharide (LPS) layer on the outer surface of the cellular membrane. The saturated fatty acids on LPS bind to the negative ions present on the membrane backbone. This renders LSPs to have high affinity towards cations. This allows the permeation of polycationic antibiotics into the cytoplasm. Also, cations such as Mg^{2+} and Ca^{2+} can act as electrostatic linkers to bind adjacent LPS chains [9.494]. However, this also makes LSPs to be highly susceptible towards cations and it has been reported that even simple cations can bind to LSP and can induce weakness in the membrane's backbone, leading to disintegration of the membrane and can lead to loss of cellular viability [9.494]. Now the effect of Ag NPs on microorganisms can be looked at.

The severe and irreparable damage caused by silver NPs to the cellular membrane [9.474, 485, 495] leading to the accumulation of NPs in the cytoplasm [9.474] has been investigated in detail. The damage these Ag NPs bring to cells stems from this and is not due to their toxicity [9.485]. This can be easily understood by the significant amount of pits formed after treatment. Another requirement of Ag NPs to have good biocidal activity is that they should be supported to have a considerable amount of antibacterial effects. Generally, cellular proteins, which help cells to guard against metal toxicity, bind to the NP surface, leading to the aggregation of NPs. In this aggregated state the NPs

become immobile [9.474]. The size of the NP particle plays an important role in the permeation of NPs into the cell, and small NPs are expected to penetrate across the cell membrane easily [9.484, 485]. Consequently, the biocidal activity of Ag NPs is also dependent on their size and shape. For example, compared to NRs and spherical particles, triangular nanoplates were found to have more activity. The crystal structure of the surface of the NPs can also influence the activity. It is understood that bacteria will interact more with high atom density (111) crystal planes [9.484]. Hence, a crystal with a larger number of (111) planes will demonstrate higher antibacterial activity [9.485].

The formation of superoxide (detected by the dismutation activity of superoxide dismutase) has been also proposed to be a reason for the antibacterial activity. It was also found that the addition of dismutase resulted in a reduction in antibacterial activity [9.496].

Another opinion suggests that the chemistry of silver ions is important in the antibacterial effect of silver NPs. Study showed that oxidized silver NPs are nontoxic towards *E. coli* strains, pointing towards the importance of chemisorbed Ag^+ ions in determining silver NP toxicity [9.486].

Studies showed that Ag NPs interact with the glycoproteins of HIV-1 and particles greater than 10 nm attach to the viral envelope. HIV cell infection also occurs due to the binding of glycoproteins with receptor sites on host cells. The sulfur-bearing residues on the protein surface actively participate in the binding process with Ag NPs and make the glycoproteins incapable of binding with host cells, deactivating the HIV virus [9.487].

The stabilization of Ag NPs in organic media such as plastics, oils, etc., is also important to attain optimum antibacterial action. There are two major approaches for this:

1. Synthesis of organic-soluble Ag NPs via different methods, for example, polymerization of benzylthiocyanate on silver NPs [9.497].
2. Preparing Ag NPs directly in vegetable oil by reduction of the metal salt by oxidative drying process in oils [9.498].

Ag NPs and their antibacterial properties have also been utilized for making bacteriostatic separation membranes [9.499–501]. Biofouling and inability to remove viruses are recurring problems in many membrane-based technologies. Thus, Ag NPs can contribute greatly to this area and incorporation of Ag NPs

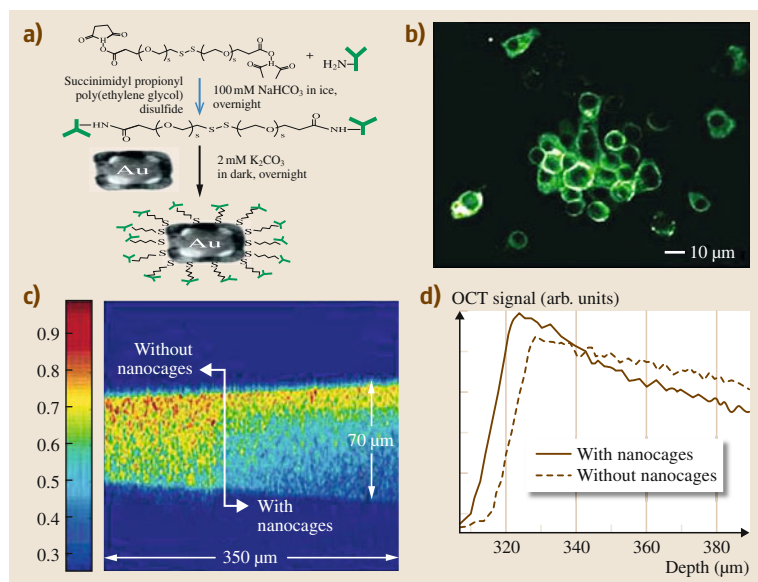

Fig. 9.41 (a) Schematic illustration of the protocol used to conjugate antibodies to the surface of Au nanocages. (b) Fluorescence image of SK-BR-3 cells whose surfaces were treated with anti-HER₂ antibodies, followed by incubation with fluorescence-labeled IgG. (d) OCT signals on log scale as a function of depth (after [9.503])

onto the membrane solves both problems. The loading can be done via two processes namely, addition of silver in zero-valent form or reduction of silver ions in the membrane casting solution. Addition of Ag NPs improved the bioresistance as well as the permeability [9.500]. Investigations pointed out that the biocidal properties of silver NP loaded membranes are due to the leaching of Ag⁺ ions from the NPs [9.502].

Size and shape-dependent physical and chemical properties of anisotropic nanomaterials make them attractive candidates for various applications. The higher efficiency of these particles over spherical NPs has been demonstrated in various applications. Hence, a few of the important applications of different kinds of anisotropic nanostructures are mentioned below. This section does not provide a comprehensive review of the literature.

9.7.2 Bioconjugation and Labeling

Functionalization of NPs with biological entities can increase their biocompatibility and thus improve their utility for targeting cancer cells. Hafner et al. stabilized, conjugated to antibodies, and characterized GNRs for biological applications. To this end, the stabilizing surfactant bilayer surrounding GNRs was replaced with thiol-terminated methoxypoly(ethylene glycol). Bioconjugation of GNRs was carried out using a heterobifunctional crosslinker and the antibody activity was confirmed by a strip plate assay. Antibody-functional-

ized NRs were conjugated to murine macrophage cells by Cortie et al. [9.504] to study their photothermal properties. Bioconjugation of GNRs with phosphatidylcholine for controlled release of plasmid DNA by NIR radiation was reported by Takahashi et al. [9.505]. Nanocages made of gold were also bioconjugated with entities including antibodies, nucleic acids, and small-molecule inhibitors. These were used to target cancer cells for early-stage diagnostics and thermal therapy of tumors [9.506]. Figure 9.41a shows a schematic illustration of the procedure used to conjugate antibodies onto the surface of Au nanocages. The molecular specific binding of these cages were tested on breast cancer cell line SK-BR-3, which overexpresses epidermal growth factor receptor 2 (EGFR2 or HER2) [9.506]. The monoclonal anti-HER2 antibody from a mouse was anchored onto cancer cells by incubating the cells and the antibody. Secondary antibodies (anti-mouse immunoglobulin G, IgG) were immobilized on gold nanocages in a buffer solution (Fig. 9.41). When the two solutions came into contact, SK-BR-3 cells conjugated with anti-HER2 antibodies became anchored on the cages. A uniform green color, indicating homogeneous distribution of the primary anti-HER2 antibody on the cell surface, was seen in the fluorescence image (Fig. 9.41b).

9.7.3 Optical Contrast Agents

Anisotropic noble metal NPs are ideal candidates as contrast agents for NIR imaging applications due to

their strong SPR, biocompatibility, ease of bioconjugation, and large scattering cross-section [9.506, 507]. The strong, tunable SPR features in the NIR region and smaller size of Au nanocages make them attractive contrast agents [9.506]. Gold nanocages were used as optical contrast agents in the OCT imaging on phantom samples. OCT imaging (Fig. 9.41c) was conducted using a 7 fs Ti:sapphire laser with a wavelength of 825 nm and a bandwidth of 155 nm. The presence of Au nanocages significantly improved the spectroscopic imaging contrast for tissues. The high absorption cross-section ($2.9 \times 10^{-20} \text{ m}^2$ at 800 nm) exhibited by the Au nanocages was about five orders of magnitude stronger than the conventional dye indocyanine green. This emphasizes the usefulness of these structures for OCT imaging. Figure 9.41d shows the log of the OCT signal as a function of depth.

9.7.4 Photothermal Therapy

Living cells being extremely temperature sensitive can be adversely affected by an increase of a few degrees and can even lead to cell death. Anisotropic NPs with NIR absorption can be used for photothermal therapy where heat is generated by plasmonic absorption [9.509, 510]. Moreover, these particles can function as dual imaging/therapy capable entities. Several anisotropic NPs including NRs, nanocages, nanoshells, and nanostars have demonstrated a good NIR absorbing capacity which can be used for photothermal therapy [9.259, 504, 506, 508, 511–516]. Selective bioconjugation of Au nanocages can cause targeted delivery of these systems into cancer cells where they can produce a local temperature rise that can provide a therapeutic effect on cancer cells [9.260, 503, 506, 508, 511, 512, 514]. As mentioned in Sect. 9.7.2, the large absorption cross-sections of Au nanocages can aid these structures to covert absorbed photons into phonons. This results in an increase in the temperature of the system. Using an ultrafast laser-induced heating process, Ag nanocages can create extremely high lattice temperatures [9.514]. Such therapy is less invasive than chemotherapy or surgery and holds strong promise as a novel form of cancer treatment. Xia et al. demonstrated the photothermal destruction of breast cancer cells in vitro using immunotargeted Au nanocages [9.259]. Gold nanocages (with an average edge length of $65 \pm 7 \text{ nm}$ and an absorption peak at 800 nm) were conjugated with anti-HER2, which enabled the specific targeting of breast cancer cells (SK-BR-3) [9.508, 513, 514]. When the targeted cells were irradiated with a pulsed

Fig. 9.42a–d SEM images of SK-BR-3 cells targeted with immuno-Au nanospheres (a) and nanocages (b). SEM images at higher magnification (*insets*) reveal that the *bright spots* in the SEM images are indeed nanospheres and nanocages, respectively. The *scale bar* in the *insets* represents 500 nm. (c) TEM image of a microtomed SK-BR-3 cell conjugated with immuno Au nanocages. (d) Typical flow cytometry graph indicating how the forward scatter (*x*-axis) and right angle (RA) scatter (*y*-axis) can be used to differentiate the size difference between beads and cells (after [9.508])

NIR laser, photothermal heating resulted in cell death. Treatment conditions such as the power density, the duration of laser exposure, and the response time after irradiation can be varied to achieve effective destruction of cancer cells. Cells targeted with Au nanocages responded immediately to laser irradiation, and irreversible cellular damage occurred at power densities greater than 1.6 W/cm^2 (Fig. 9.42). As the time of exposure increased, more and more cell death was observed.

Salem et al. demonstrated a novel nonviral gene therapy approach using multisegmented metal NRs [9.517, 518]. Cancer treatment can make use of NTs as well. Hyperthermic treatments can be carried out using NTs, which also possess large NIR absorption. Because the surface of NTs is flat, it facilitates high contact between the NTs and cancer cells, which in turn helps to reduce the required exposure time. Hence even at low dosage NTs can be effectively delivered into cancer cells, and the low dosage reduces the metal toxicity as well.

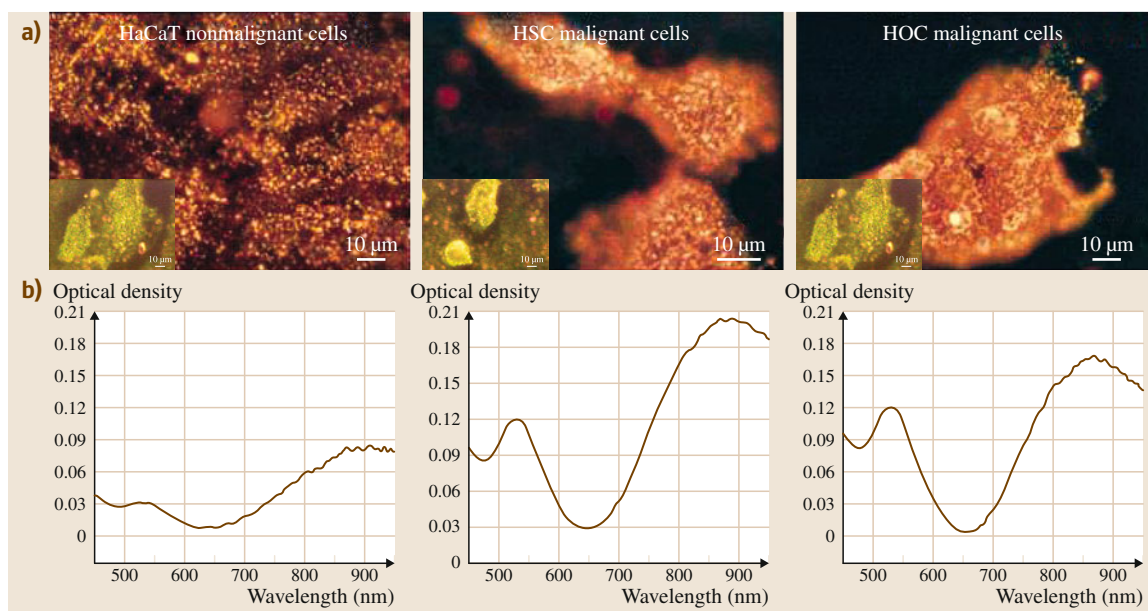

Fig. 9.43 (a) Light scattering images of anti-EGFR conjugated Au NRs after incubation with cells for 30 min at room temperature. (b) Average extinction spectra of anti-EGFR conjugated Au NRs from 20 different single cells for each kind. *Insets* show the corresponding light scattering images of anti-EGFR-Au nanospheres after incubation with cells for 30 min at room temperature (after [9.519])

9.7.5 Cancer Cell Imaging

Using dark-field optical microscopy and TPL microscopy, individual anisotropic NPs can be imaged due to the strong SPR exhibited by them. They are ideal candidates for biomedical imaging because of the large scattering cross-section [9.510]. GNRs in particular, are well suited for cancer cell imaging due to their strong absorption and scattering in the NIR region (650–900 nm) [9.509, 510, 517–523]. Huang et al. used GNRs functionalized with negatively charged PSS for cancer cell imaging [9.519]. The PSS coated GNRs on mixing with an antibody solution in 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) buffer, conjugated with anti-epidermal growth factor receptor (anti-EGFR) monoclonal antibodies. Two malignant cells, namely HOC 313 clone 8 and HSC 3, and one nonmalignant Ha-Cat cell were used in the experiment. The anti-EGFR antibody-conjugated NRs showed higher affinity to malignant cells due to the over-expressed EGFR on the cytoplasmic membrane and bound specifically to the surface of the malignant-type cells. The light scattering images of anti-EGFR-conjugated GNRs after binding to malignant and nonmalignant cells are shown in Fig. 9.43.

The dominant orange color in the image corresponds to the surface plasmonic enhancement of the longitudinal oscillation in the NIR of GNR. After antibody conjugation, GNRs only interact with the malignant cells. The nature of the interaction is distinguished by light scattering imaging; Fig. 9.43 shows the quantity of NRs bound to the cell. From the extinction spectra, it is clear that the cancerous cells with nanocages have twice the intensity compared to noncancerous cells. The difference in interaction of anti-EGFR-conjugated GNRs with malignant (target specific) and nonmalignant (nonspecific random) cells gives rise to this difference in intensity. Wang et al. showed that GNRs, when excited at appropriate wavelengths (corresponding to LSPR peak position) using a two-photon scheme, can produce a luminescence signal 58 times stronger than the fluorescence signal from a rhodamine molecule [9.524]. Durr et al. used GNRs as contrast agents for imaging of cancer cells and the huge TPL of GNRs was found to be excellent for this application [9.525]. Gold nanocages are also known to exhibit a broad two-photon photoluminescence band (from 450 to 650 nm) when excited by a 800 nm Ti:sapphire laser. Use of Au nanocages as optical imaging agents for two-photon microscopy has recently been demonstrated by Xia et al., who

(d) SERS spectra collected on LB films of each of the nanocrystal shapes of 10^{-6} M arsenate solution. Peaks at 800 and 425 cm^{-1} can be assigned to Na_2HAsO_4 . (e) SERS response of octahedra LB arrays coated with various organic species: benzenethiol (BT), hexadecanethiol (HDT), mercaptodecanoic acid (MDA), and PVP (after [9.466])

directly examined the uptake of antibody-conjugated and PEGylated Au nanocages by U87MGwtEGFR cells [9.512].

9.7.6 Surface-Enhanced Raman Scattering Substrates

Ultrahigh sensitivity and specificity are the marked features of SERS. So it is a well-established technique and an attractive tool for trace level chemical detection. An excellent number of fine reviews are available on this topic in the literature [9.414, 417, 464, 526–534]. The SERS signal sensitivity strongly depends on the shape of the NPs [9.526, 527]. This technique can be used for the detection of arsenate and arsenite in aqueous solutions with a detection limit of 1 ppb (Fig. 9.44d), an order of magnitude below the standard set by the World Health Organization (WHO) [9.466, 535]. Yang et al. successfully demonstrated this by using LB assemblies of various polyhedral Ag nanocrystals (Fig. 9.44a–c), made by a polyol process. Octahedra LB arrays coated with various organic species such as benzenethiol, hexadecanethiol, and mercaptodecanoic acid have very good SERS response, as is shown in Fig. 9.44e. We know that contaminated ground water becomes a curse to public health in most developing nations. So there is a need for a reliable and simple device to detect arsenic in ground water. This SERS substrate has proven

to be a good solution for the above crisis. It is reliable, reproducible, highly portable, and could be easily implemented for field detection. Another SERS substrate NP that exhibits strong SERS activity is AuNF. By packaging RhB@AuNF particles with denatured BSACE94 molecules the AuNF particles could be developed into Raman-active tags, whose application in living cells was demonstrated by using the RAW264.7 macrophage cell line [9.536, 537].

Real-time detection of biomolecules using SERS has also been reported [9.528–530]. It is known that SERS activity varies depending on several factors. For example, Nogami et al. reported that triangular plates having sharper corners and edges have higher SERS activity [9.531]. Similarly, silver nanoplates in aggregated form have higher SERS activity than single-form ones due to strong electromagnetic coupling between neighboring nanoplates [9.51, 538]. When we consider anisotropic metal NPs, it is clear that their unusual LSPR properties and sharp corners on the surface are the factors contributing to higher SERS activity. These sharp corners can create a more localized electric field in comparison with spherical particles [9.535, 537].

9.7.7 Superhydrophobic Surfaces

The wettability of a surface depends on the chemical composition and morphology of that surface.

Some surfaces have a very high water repellency. The creation of a local geometry with a large geometric area relative to the projected area or the use of roughness combined with hydrophobic coatings can result in increased surface hydrophobicity. Such superhydrophobic surfaces have many advantages. Water droplets that are in contact with such surfaces (contact angle $> 150^\circ$) form nearly spherical beads. They are self-cleaning surfaces in which contaminants of any type, whether inorganic or organic, adhere to water droplets and will be removed when the water droplets roll off. Superhydrophobic surfaces can be made by using anisotropic nanomaterials. A single-crystalline Ag dendritic film (thickness $\approx 10\mu\text{m}$) when functionalized with a SAM of *n*-dodecanethiol can form a superhydrophobic surface with a contact angle of $154.5 \pm 1.0^\circ$ and a tilt angle lower than 2° [9.188]. From contact angle measurements, we can infer that the presence of Ag crystallites on the substrate increases hydrophobicity compared with substrates without Ag crystallites (Fig. 9.45). We can grow Ag nanoplates on GaAs substrates by direct reaction between aqueous solutions of AgNO_3 and the GaAs surface, and it then shows the Lotus effect [9.189]. These Ag nanoplates can be coated with 1-hexadecanethiol molecules to decrease the surface energy of Ag plates. One of the major advantages of this methodology is that we can change the wettability of such a surface. This is done by controlling the dimensions and nanoscale surface roughness of individual nanoplates using appropriate variation of the reaction conditions.

Fig. 9.45 (a) SEM image of Ag crystallites. (b) Photograph of water droplets on the Ag dendritic film surface, Ni surface, and Cu surface. All surfaces were modified with *n*-dodecanethiol (after [9.188])

9.7.8 Mercury Sensor

Mercury, a highly toxic pollutant which is harmful to the environment, is released from various sources such as power plants, burning fossil fuels, etc. Exposure to high Hg can harm our organs and affect the immune system. So it is important to monitor Hg levels in aquatic ecosystems. Owing to the amalgamation of gold and mercury, GNRs can selectively detect the presence of mercury in tap water samples at the ppt level [9.379]. The main highlight of this method is that it is very fast and the entire sensing process takes place in less than 10 min, with no sample separation and even ultralow levels of Hg can be detected very easily. The amalgamation process of Hg with GNRs is schematically represented in Fig. 9.46. Mercury was added into the growth solution during the synthesis of GNRs and it was found that the AR of the GNRs is inversely propor-

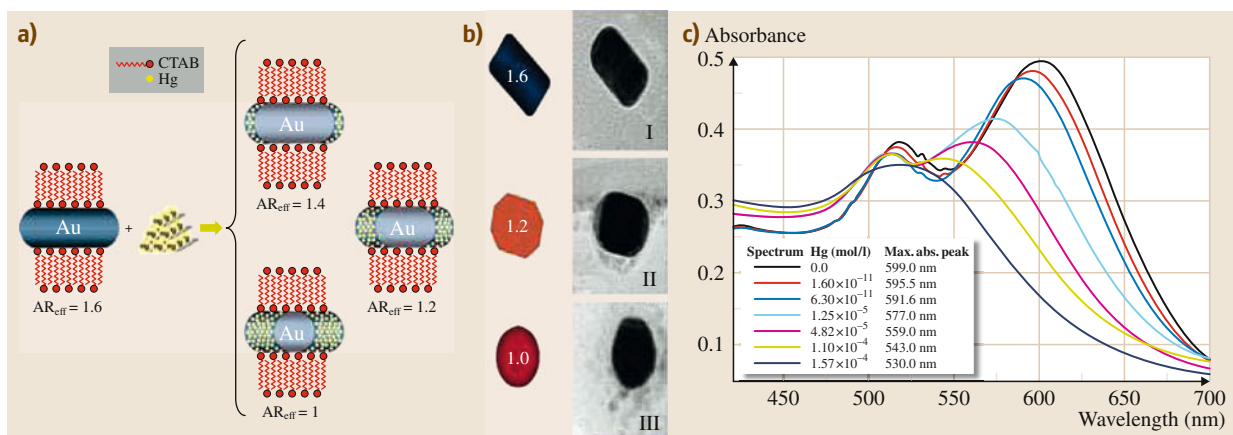

Fig. 9.46 (a) Schematic representation of the amalgamation of Hg with GNRs. (b) TEM images of GNRs in the absence and the presence of Hg. (I) no Hg, (II) 1.25×10^{-5} M, and (III) $1.57 - 4$ M of Hg^{2+} . (c) UV/Vis absorption shift in the concentration range between 1.6×10^{-11} and 6.3×10^{-11} M of Hg(II) (after [9.379])

tional to the concentration of Hg^{2+} at constant NaBH_4 concentration. A quantitative analysis can be made by connecting the wavelength shift and the mercury concentration (Fig. 9.46). The detection limit of Hg in tap water for this method was 6.6×10^{-13} g/l.

9.7.9 Infrared Absorbing Material

NIR absorbing films based on gold can be effectively used for blocking IR radiation. NP-based methods have a high efficiency and are economically more viable compared to other methods. Thus they can be used as an alternative way of blocking IR rays instead of reflective coatings. We can develop IR filters using nanomaterials with NIR-IR absorption capacity. Using a prototypical device, it was demonstrated that gold mesoflowers (MFs) can be successfully used to reduce the temperature rise in an enclosure exposed to daylight [9.539]. They were able to absorb a significant portion of heat. Along with a blank glass substrate as the control, a monolayer and a bilayer of MF-coated glass slides were used to take the heat absorption measurements. Results showed that the MF-coated glass (monolayer) gave an average temperature inside the cardboard box which was lower by 2°C , whereas the bilayer coated substrate showed a reduction of 4.3°C compared to the blank glass substrate. In future this can lead to the application of such NIR absorbing materials to make heat absorbing optical coating of windows [9.419, 539].

9.7.10 Plasmonic Waveguides

Another application of nanomaterials is in the area of photonic devices. They can have the role of waveguides if we carefully fabricate them to guide electromagnetic energy. This can be realized with lateral mode confinement below the diffraction limit of light, which is not possible through conventional waveguides or photonic crystals. Chains of closely spaced metal NPs that convert the optical mode into nonradiating surface plasmons can be prepared through electron beam lithography or self-assembly techniques. Maier et al. experimentally demonstrated that closely spaced silver NRs can guide electromagnetic energy from a localized subwavelength source to a localized detector over a distance of about $0.5\ \mu\text{m}$ [9.540]. The waveguide structures have individual AgNRs (90 nm – long and $30\ \text{nm} \times 30\ \text{nm}$ width/thickness) with spacing of 50 nm between adjacent particles. An increase in near-field coupling between the particles was created due to the perpendicular orientation of the NRs (long axis) with re-

spect to waveguide chain axis. The waveguides used the tip of a scanning near-field optical microscope. For this, a dye laser (wavelength of 570 nm) corresponding to the single-particle resonance was used. The energy transfer through the waveguide was probed using fluorescent nanospheres made up of carboxyl-coated polystyrene. Fluorescent nanospheres placed on top of a waveguide at a distance from the excitation source became excited (illustrated by the dye emission from the fluorescent particle) by the local excitation given to the NR, which proves the propagation of these excitons along the NR array. The study demonstrated that energy attenuation lengths of several hundred nanometers is possible through nanostructure arrays pointing towards the utility of these plasmon waveguides as functional end-structures in integrated optical devices [9.540].

9.7.11 Biosensors

Anisotropic NPs with strong SPR features, which are greatly influenced by the changes in local environment, can be used for sensing [9.541]. GNRs with high-value shape factor (surface curvature), are ideal candidates for plasmon sensing. A multiplex biosensor assay for different targets was constructed using GNRs by Yu and Irudayaraj [9.542]. GNRs of different ARs were conjugated with the IgG of humans, rabbits, and mice using the 11-mercaptopundecanoic acid linker. The shifts in SPR wavelengths of these NRs were used to probe their coupling with respective complements (anti-IgGs). Detection of multiplex surface markers of breast cancer cells by the use of antibody-conjugated GNR molecular probes also employs a similar strategy [9.543]. A glucose sensor based on the layered superstructure of gold nanooctahedra was demonstrated by Choi et al. [9.544]. The superstructure was fabricated via a molecularly mediated assembly approach. Compared to spherical particles/glucose oxidase (GOx) system, the single-layered Au nanooctahedra/GOx system exhibited a greater voltammetric response under same conditions pointing towards the dependence of the sensor activity on the shape of the Au particles used. The Au nanooctahedra-based glucose biosensor demonstrated a high level of sensitivity in the range of $0.349\ \mu\text{A}/\text{mM}$ and fast response (within few seconds) with a wide response range (between 0.125–12 mM) [9.544].

9.7.12 Photovoltaic Devices

Photovoltaic devices consisting of nanocrystals rely on the electron acceptor capability of constituent NPs from

conjugated polymers. However, the limitation of electron extraction through the nanocrystal is a big problem of photovoltaic devices made with spherical nanocrystals [9.39, 40]. The use of anisotropic structures (e.g. NRs) instead of spherical nanocrystals can give significantly higher efficiencies because of the smaller number of interparticle hops necessary for electrons to leave the device [9.545]. Generally, either TiO₂ [9.546] or ZnO [9.547] NPs are used for this application. Recent studies indicate that noble metal nanosystems can be also used for this application. Incorporation of noble metal NPs are reported to increase the efficiency of solar cells containing ZnO [9.548] and TiO₂ [9.549, 550] nanomaterials. The overall transport properties of the system will become modified by the incorporation this nanophase into the composite. Moreover, this will also permit optical tunability by adjusting the size of the metal NPs present. The overall absorption of light is also believed to be enhanced by the presence of noble metals.

Hasobe et al. pioneered works in this direction in 2003 [9.551]. Organic solar cells containing self-organized porphyrin (donor), fullerene (acceptor), and SnO₂ electrodes containing Au NPs were prepared. A large enhancement in the photoelectro-

chemical performance and a broader photoresponse in the visible and IR ranges were demonstrated by the Au NP containing cells. A self-assembled composite of Au NP and porphyrin was used for photovoltaic applications by *Yamada* et al. [9.552]. *Kim* and *Carroll* did a detailed study regarding the enhancement of poly(3-octylthiophene)/fullerene bulk heterojunction photovoltaic devices by gold and silver NPs [9.553]. *Derkacs* et al. reported an increase in the efficiency of amorphous-silicon solar cells by metallic NPs [9.554]. Others have reported similar enhancement in the case of polymer-based voltaic cells [9.555, 556]. Dye-sensitized solar cells (both iodide/triiodide electrolyte-based and solid-state) made up of core-shell Au-SiO₂ NPs, which help in plasmon-enhanced light absorption leading to enhanced photocurrent and efficiency have been demonstrated by *Brown* et al. [9.557]. *Yildiz* et al. reported a solar cell consisting of oligoaniline crosslinked Au/CdS NP arrays on electrodes with enhanced photocurrent efficiency [9.558]. *Isikawa* et al. investigated the effect of the SPR of Ag NPs on dye-sensitized solar cells [9.559]. An increased photovoltaic efficiency for tandem ultrathin-film organic photovoltaic cells was found by the incorporation of Ag NPs [9.560].

9.8 New Gold and Silver Materials – Quantum Clusters

The dimensions of noble metal NPs are decreasing. In the very recent past, subnanometer particles and their associated properties have attracted intense interest. Quantum clusters (QCs) are a new class of materials made up of a few to tens of atoms, giving core sizes below 1 nm, which exhibit unusual physical and chemical properties due to their molecule-like nature [9.561, 562]. QCs act as a bridge between molecular and NP behaviors, and they possess properties that are entirely different from both of these size regimes. They possess an intermediate chemical composition between the bulk and molecular regimes, with an electronic band structure modified into discrete electronic states as a result of quantum confinement. Just as in the nanometer regime, the subnanometer regime is also dominated by optical properties. While it was absorption for the former, it is luminescence for the latter. QCs exhibit strong and core size-dependent, tunable photoluminescence properties. They show characteristic absorption features and are also photostable. The quantum yield of gold QCs is several orders of magnitude higher than

that of bulk gold. The photoluminescence, photostability, and biocompatibility exhibited by gold QCs make them potential materials for use in many biorelated applications such as labeling, cell imaging, drug delivery, detection, etc. [9.562]. Coupled with the possibility of chemical functionalization and due to the absence of cytotoxicity, these materials are beginning to enter biomaterials; the possibility that such clusters can directly nucleate in proteins expands the scope of this application. The clusters that have been investigated using the tools of gas-phase spectroscopy are now being made in the condensed phase. Adaptation of the properties of gas-phase clusters to their condensed-phase analogs will enrich this area in the years to come. Newer spectroscopy and mass spectrometry tools would enable the exploration of these novel properties. Several of the phenomena exhibited by such materials cannot be fully studied without comprehensive theoretical calculations. Newer insights are expected on the structure, properties, and dynamics of these systems from such studies. Although several types of cluster have been synthesized,

very few have been fully characterized by crystallography (Au_{25} , Au_{40} , Au_{102}).

Monolayer-protected gold QCs can be synthesized by various methods [9.561, 563]. They can be directly synthesized from precursor ions (Au^{3+}), which are reduced by a reducing agent (e.g., NaBH_4) in the presence of stabilizing ligands such as thiols, amino acids, proteins, dendrimers, etc. [9.562, 564]. A series of glutathione-capped gold QCs have been synthesized by reducing gold ions in the presence of glutathione, followed by their separation using the polyacrylamide gel electrophoresis method. A new QC can be made from another QC by treating it with the appropriate ligands. QCs are also synthesized by core etching processes [9.563]. In this process, core etching of NPs using appropriate ligands such as dendrimers, thiols, Au^{3+} ions, etc., results in the formation of QCs. Gold clusters are also highly stable at ambient conditions.

Recently our group devised a strategy for synthesis of Au QCs with the aid of cyclodextrin (Fig. 9.47b) [9.564]. They showed interesting solvent-dependent luminescence, indicating a large number of applications in sensing and security. In the case of gold QCs, the electronic bands resolve into discrete energy levels which resemble those of molecules; hence, they can be treated as molecular entities. For example, Au_{25} shows multiple molecular-like transitions in its optical spectrum [9.565]. The luminescence quantum yield of synthesized gold QCs ranges from 0.1 to 25%. Although the mechanism of luminescence in QCs is not fully known, it is believed that the emission originates from radiative intraband transitions within the sp bands, across the HOMO–LUMO gap. As the size of the cluster decreases, the spacing between the discrete states increases, which leads to a blue-shift in the emission of smaller QCs as compared with their larger analogs. Since QCs are biocompatible and luminescent, they are promising candidates for biorelated applications such as targeted imaging of cancer cells, biolabeling, drug delivery, etc. [9.561, 566]. Recently, the cluster formation process inside a protein was studied using various spectroscopic techniques [9.567]. These clusters can easily be conjugated with biological molecules, further enhancing their application potential. Most of the metal quantum clusters emit in the NIR region and hence they can be used for two-photon imaging with IR excitation [9.563]. Two-photon emission of Au_{25} observed at 830 nm with excitation at 1290 nm can be useful for two-photon imaging [9.561]. QCs also exhibit electroluminescence at room temperature and hence provide facile routes to produce strong single-photon emitters [9.561].

The luminescence of gold QCs is exploited for metal ion sensing [9.568]. Fluorescent gold QCs can be used to sense mercury(II) based on fluorescence quenching through $\text{Hg}(\text{II})$ -induced aggregations [9.569]. Quantum clusters are very good catalysts [9.561]. As the crystal structures of QCs are known, it is possible to correlate the particle structure with catalytic properties. It was found that metal oxide (e.g., Fe_2O_3 , TiO_2)-supported gold QCs show higher catalytic activity and yield compared with unsupported QCs [9.561].

Silver analogs of these fascinating materials, however, are more reactive compared to their gold counterparts. Hence, comparatively fewer reports exist. Nevertheless, diverse methods have been reported for the preparation of Ag clusters [9.570] and most of them are highly luminescent in both solution and the solid state. The pioneering effort in this direction was done via gas-phase and low-temperature matrix-isolation methods [9.571, 572]. The formation of excited Ag_2 and Ag_3 clusters and the resulting chemiluminescence during Ag condensation with Ar has also been reported [9.573]. Nonluminescent silver clusters have been synthesized in frozen solutions and zeolites [9.574]. Diverse methods such as radiolytic reduction [9.575, 576], sonochemical synthesis [9.577, 578], chemical reduction [9.579–583], photoreduction [9.584], etc. have also been employed for synthesis of Ag clusters. A solid-state route for synthesis of Ag_9 clusters was recently reported by Pradeep et al. (Fig. 9.47a) [9.579]. The same group also made silver clusters by following an interfacial method (Fig. 9.47c) [9.585, 586].

Due to the higher reactivity of silver clusters, they are prone to aggregation and the resultant growth to form larger clusters/NPs. Usually this problem is avoided by using some preformed templates or capping agents to synthesize stable entities [9.587]. Both organic and inorganic scaffolds are being used for this purpose. Organic scaffolds for fluorescent silver QCs were first employed by the group of Dickson in 2002, who employed dendrimers as scaffolds [9.588]. Since then, several organic scaffolds such as dendrimers, polymers, short molecules containing both carboxylic groups and thiols groups, DNA, proteins, and peptides have all been employed for this purpose. Kumacheva et al. employed poly(*N*-isopropylacrylamide-acrylic acid-2-hydroxyethyl acrylate) microgel particles as a scaffold for preparing luminescent silver QCs [9.584]. The use of acrylates for synthesis of small silver QCs, which do not exhibit fluorescence, by applying γ radiation was reported earlier by Ershov and Henglein [9.589]. It has also been reported that, as compared with small poly-

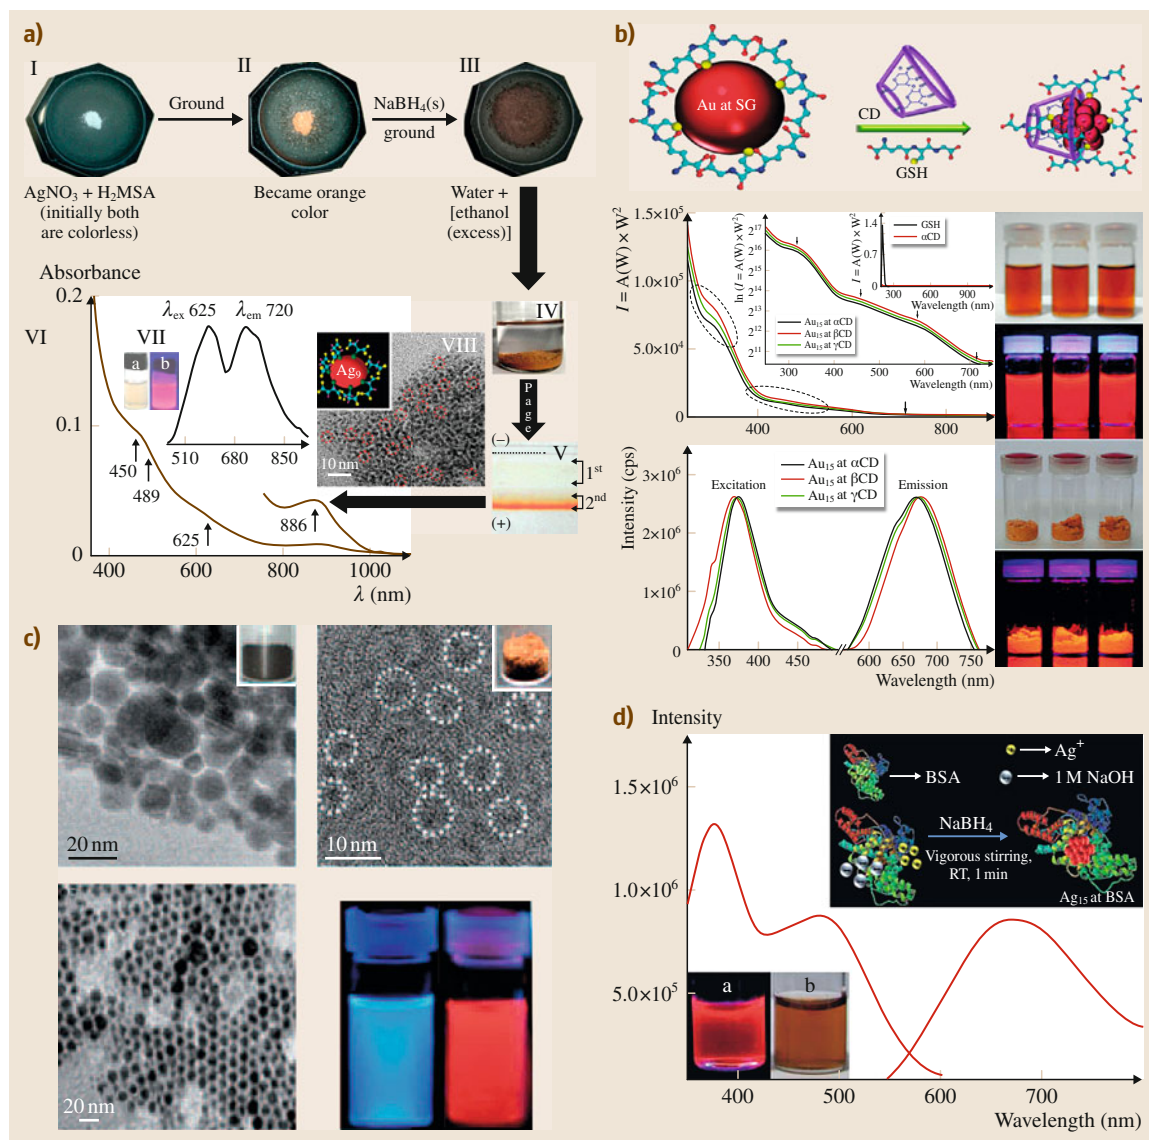

Fig. 9.47 (a) Scheme of preparation of Ag clusters synthesized through solid-state route and their characterization. (b) Au clusters synthesized using cyclodextrin, UV/Vis spectrum, and luminescence (CD: cyclodextrin; GSH: glutathione). (c) TEM image of Ag clusters synthesized by interfacial etching method and photograph showing the luminescence. (d) Scheme for the preparation of BSA-protected silver clusters and their luminescence characterization. From the authors' laboratory

mers, a high density of COOH-groups is better for the formation of fluorescent silver QCs [9.590]. Recently, small molecules having carboxylic or thiol functionalities were also used for synthesis of small clusters. Molecules such as captopril and glutathione [9.591], and dihydrolipoic acid [9.592] are reported to produce

silver clusters with weak fluorescence. Pradeep and Bhaskara Rao used MSA as a scaffold for the preparation of Ag_7 and Ag_8 QCs via interfacial etching of large NPs in several aqueous/organic biphasic systems [9.586]. Ag_9 clusters have been synthesized using a solid-state route as well [9.579].

The use of biomolecules as scaffolds is a step towards developing green chemistry protocols for making quantum clusters, and it also enables the clusters to permeate into cells. Due to their luminescence property, molecular events such as replication of DNA and other genomic events happening inside cells can be visualized, measured, and tracked. Linear oligonucleotides having 12 bases were reported to be excellent scaffolds for preparation of Ag clusters [9.593–596]. It was also reported that, of these bases, Ag has more affinity towards cytosine [9.597] and guanine [9.598] residues. Efforts to use proteins as scaffolds for silver clusters due to the high affinity of silver to proteins have also been reported. Enzymes such as bovine pancreatic α -chymotrypsin (CHT) were used as templates for preparation of fluorescent silver clusters [9.599]. Cluster preparation by photoreduction in the presence of thioflavin T (ThT) has also been reported [9.600]. Synthetic oligopeptides also are being used for the preparation of silver clusters [9.601, 602]. A supramolecular hydrogel made up of dipeptides was also employed for synthesis of Ag clusters [9.603]. Proteins are also very actively used as scaffolds. Similar to dendrimers, the cage effect of the protein stabilizes the clusters and enhances their optical properties. Recently, Liu et al. synthesized BSA-protected Au and Au@Ag clusters using a sonochemical approach [9.578]. A protocol using BSA as the template for synthesis of Ag clusters was developed by our group recently (Fig. 9.47d) [9.604]. The conversion of Ag@citrate NPs to luminescent quantum clusters was also reported by our group [9.605]. The chemical synthesis of these systems has advanced tremendously. It

is possible to create precisely controlled alloy clusters (Ag_7Au_6) through chemical means, as illustrated by our group very recently [9.606].

Inorganic templates such as glasses have also been used for preparing quantum clusters. This involves several steps. The first step involves doping of the glass with Ag^+ , followed by activation by external means in the second step. The activation can be done through laser irradiation [9.607, 608], synchrotron irradiation [9.609], thermal annealing, or controlled quenching of the melt [9.571]. Zeolites have also been employed for synthesis of clusters [9.610, 611]. Here also, activation can be done by various means including heat treatment [9.612], UV light excitation [9.611], and two-photon excitation [9.613].

The application possibilities of these new nanosystems are enormous, and their exploration is in its infancy. One of the most obvious applications of these systems is in biology, especially in bioimaging [9.563, 568, 614, 615]. They have shown tremendous promise in catalysis as well [9.616–618]. These materials have been investigated for use in water purification as well. Their reactivity with heavy metals was recently explored by our group, and it was proved that the chemistry is essentially similar to that of corresponding larger NPs [9.440]. It has been demonstrated that such clusters are useful for detecting heavy metals in water as well [9.619]. The feasibility of using these materials in composites for novel applications such as antibacterial scaffolds has also been explored [9.620]. However, the authors feel that these materials are going to make a large impact in many fields, including water purification, ultrasmall sensors, diagnosis, and therapy.

9.9 Conclusions

Nanomaterials in general and noble metal NPs in particular are interesting materials for a large number of applications. This chapter illustrates the potential of noble metal NPs in various fields. The diversity and tunable properties of noble metal NPs make them superior over other categories of NPs for several key applications. In comparison with other nanoscale systems, noble metal NPs are much more stable and exhibit much less cytotoxicity. Hence, the applicability of these NPs is far greater than that of other nanosystems, especially in biology. However, most properties of many of these nanosystems, especially the anisotropic analogs, have been studied only to a limited extent, and more work is needed to understand them better.

There are many promising avenues in terms of their medical and material science applications, and consistent efforts are needed to bring these to reality. The properties of gold and silver NPs and clusters are extremely sensitive to their size and shape. Detailed understanding is possible only through precise computational analyses. Rapid and sensitive responses of these NPs would be useful for developing new sensing devices. Recent research and understanding of the use of various gold and silver NPs in cancer diagnostics and therapy have already provided a platform for the development of clinical applications in the near future. A better understanding of the kinetics and dynamics of the evolution of a single NP and the development

of a more precise kinetic theory to provide an insight into the influence of various parameters on the growth of NPs under a range of conditions are also desirable. Before using these nanosystems for various applica-

tions, especially in biology and for clinical purposes, a thorough evaluation of the cytotoxicity of NPs as a function of their size, shape, and surface coating is needed.

Nanostructures of Common Metals

Melinda Mohl, Krisztián Kordás

Since nanosized metals with magnetic features, and porous and noble metals, are discussed in other chapters of this handbook, here we present a complementary, comprehensive review on other metal nanostructures. Accordingly, this chapter is devoted to review the strategies of synthesis as well as properties of the most common transition- and post-transition-metal nanoparticles. Particular attention is paid to scalable production methods and enabled or foreseen applications of such metals, including low-melting-point lead, bismuth, tin, and indium, some of the refractories including tungsten, molybdenum, tantalum, and titanium, as well as a few more of the very commonly used metals such as copper, aluminum, and zinc. The review is expected to help the readers to get a glance at the state-of-the-art in the field and to foster new studies to overcome chal-

lenges associated typically with controlled bulk production and exploitation of this family of nanomaterials.

Looking at the Periodic Table of elements, we find about 80 natural/stable isotopes of metals that are non-magnetic and nonprecious. Among these, the alkali and alkali-earth metals (s-group) are extremely reactive, and the lanthanoids and actinoids (f-group) and some of the d-group metals are of low abundance, leaving roughly 20 elements that can be considered as practical choices for large-scale industrial use in metallic form, especially when talking about nanoparticles. Though each metal has its peculiarities, the basic rules concerning their size-dependent physical properties follow the general trends observed when talking about nanosized structures of other metals. Small crystal size can result in: increased chemical reactivity due to the relatively large number of surface atoms and vacancies at specific crystal edges and apices, melting point depression because of the large surface energy, decreased electrical and thermal conductivity due to the more pronounced electron and phonon scattering at the crystal boundaries, the appearance of molecular-like electronic states instead of

the ordinary overlapped valence and conduction bands giving rise to the onset of semiconducting/semimetallic behavior in very small clusters or very thin wires, the appearance of magnetic polarization, etc. [10.1–13].

Since the pioneering work of *Granqvist* and *Buhrman* [10.14], quite some efforts have been devoted to synthesize and study fine metal particles, and to determine how their properties, which may differ from those of their bulk counterparts, could be exploited for the benefit of various industries [10.15–23]. Synthesis methods may be divided into physical and chemical routes. Within these, we can further distinguish crystal growth with or without a template. The common feature in most of these methods is how the nanoparticles form:

1. Decomposition/reduction of precursor material or evaporation of metal atoms/clusters,
2. Formation of nuclei, and finally
3. Nanocrystal growth.

In this chapter, we select 11 metals – aluminum, bismuth, copper, indium, lead, molybdenum, tantalum, tin, titanium, tungsten, and zinc – which we consider

as the most relevant ones, and present a review on their synthesis and applications reported in the open literature.

10.1 Post-Transition Metals

Metals of the p-block elements – and in some classifications also Zn, Cd, and Hg – belong to the category of post-transition metals. Though the chemical properties of p-block metals can be very different due to the rapid decrease of their metallic character with decreasing number of periods and increasing group number, common features of these metals are their low melting point, ductility, and moderate electrical as well as thermal conductivity (except for aluminum, which has superior electron and phonon transport behavior compared with most of the metals in the entire Periodic Table of elements). In Sect. 10.1, we consider lead, bismuth, tin, indium, and aluminum, as the most frequently applied metals of the p-block elements with reasonable potential in future nanodevices [10.24, 25].

10.1.1 Lead, Bismuth, Tin, and Indium

Lead, bismuth, tin, and indium, typically known for their low melting point, ductility, and good wetting by other metals, are all predestined to be excellent soldering materials. Owing to their low Young's moduli ($E_{\text{Pb}} = 14.0$ GPa, $E_{\text{Bi}} = 31.7$ GPa, $E_{\text{Sn}} = 41.4$ GPa, and $E_{\text{In}} = 12.7$ GPa) [10.26] compared with other ordinary metals (e.g., $E_{\text{Cu}} = 110$ GPa, $E_{\text{Al}} = 68.0$ GPa, and $E_{\text{W}} = 400$ GPa), soft mechanical bonds are enabled and used in sealing, plumbing, as well as (solid-state) lubrication. The electrical properties, which depend also on the crystal size of these materials, also have some peculiarities. Lead has a relatively high superconductivity-transition temperature ($T_c \approx 6$ K [10.27, 28], one of the highest values among pure metals). Bismuth has a very high thermoelectric coefficient ($S \approx -30$ to $60 \mu\text{V/K}$ [10.29, 30], depending on crystal size) and large mean free path of carriers [10.31–36], and shows semiconducting behavior on the nanoscale [10.37–39], suggesting applications in novel electronic devices. Although many studies deal with the superconducting behavior of nanowires of tin and indium, demonstrating shape- and size-dependent [10.40–42] properties [10.43, 44], real applications of these nanostructured metals are mainly related to lead-free electronics packaging [10.45], catalysis [10.46], and batteries [10.47],

although they are also used as a sacrificial template for galvanic exchange plating [10.48] or as a starting material of the widely used tin and indium oxides and other compounds. Accordingly, a large number of different methods have been developed to generate both Pb [10.49–64] and Bi [10.31–36, 65–76] nanostructures of various shapes and sizes [10.49–56].

Lee and coworkers recently demonstrated a vapor condensation method to synthesize zero-dimensional Pb nanoparticles by evaporating high-purity lead in Ar atmosphere at 0.1–2 Torr pressure [10.57]. The particles were collected by thermophoresis using a steel plate cooled with liquid nitrogen. The mean size of the nanoparticles could be varied from 4.5 to 86 nm. Another useful route leading to nanoparticles was developed by Dang et al., in which a surfactant-assisted solution-phase approach was applied to generate nanoparticles with average diameter of 40 nm [10.53]. First, Pb granules were dispersed in stearic acid containing paraffin oil at 330 °C. Small droplets of lead were generated by a stirring force, immediately reacting with stearic acid to form a lead stearate layer around the droplet. Tribological measurements of the nanoparticles dispersed in paraffin oil showed that, even at very low concentration, the antiwear performance was markedly improved.

In a set of publications [10.49, 50], Xia and coworkers demonstrated a bottom-up approach for chemical synthesis of Pb spherical colloids by thermal decomposition of lead acetate in the presence of tetra(ethylene glycol) (TEG) and poly(vinyl pyrrolidone) (PVP). Large quantities of single-crystal Pb nanowires [10.54, 58] (Fig. 10.1a) can be obtained under conditions similar to in the aforementioned approach; however, the reaction must be performed in ethylene glycol. In comparison with the evolution of face-centered cubic (fcc) metal nanowires, ethylene glycol here only serves as a high-boiling-point solvent to facilitate thermal decomposition of the precursor, while the major function of PVP is to prevent Pb nanoparticles from aggregating in the nucleation stage. The growth mechanism (Fig. 10.1c,d)

Fig. 10.1 (a) Scanning electron microscopy (SEM) image of Pb nanowires prepared in ethylene glycol in the presence of PVP. *Inset* shows the rectangular cross-section of the nanowires. (b) SEM image of hexagonal and triangular flakes of Pb synthesized by increasing the amount of PVP. (c) Schematic image of the presumed mechanism for nanowire growth. (d) Transmission electron microscopy (TEM) image of a growing nanowire; *insets* show selected-area electron diffraction (SAED) patterns of its root and stem. (After [10.58]) ►

of these nanowires is believed to be a combination of the solution–liquid–solid (SLS) [10.59] method and the Ostwald ripening phenomenon. In addition to nanoparticles and nanowires, Pb hexagonal and triangular nanoprisms (Fig. 10.1b) have also been reported [10.55, 58]. The preparation of thin plates (thickness < 100 nm) is based on a kinetically controlled polyol process.

Another useful route to synthesize one-dimensional nanostructures is to load materials into the channels of porous membranes such as track-etched polycarbonate (PTCE), anodic aluminum oxide (AAO) or mesoporous silica membranes (e.g., MCM-41, SBA-15). Loading of these porous structures can be achieved by a wide variety of techniques, such as liquid-phase injection, vapor-phase sputtering, and chemical or electrochemical deposition. Besides porous mesoscopic membranes, crystal surfaces with specific steps and edges may also be used as templates for self-ordering nanoparticles [10.60–64]. One of the major problems associated with such template-directed methods is the difficulty in achieving single-crystalline nanowires in large quantities.

Among the physical methods, evaporation, liquid-phase injection into channels of alumina templates [10.32, 34], as well as breaking up of elongated molten filaments under shear force [10.51, 52] have been utilized to obtain nanostructures of bismuth.

Chemical growth of bismuth nanocrystals was demonstrated by a set of various chemical processes including hydrothermal reactions [10.35, 65], synthesis in reverse micelles [10.66], decomposition/reduction of organometallic precursors and inorganic bismuth salts [10.35, 65, 67, 70–72, 76], and PVP- and/or polyol-mediated syntheses [10.50, 51, 68]. Polyol-mediated methods are of great importance as they allow large-scale synthesis, and most importantly the shape and size of the particles are easy to control by adjusting the ratio of reactants [10.68]; For instance, Wang and coworkers [10.73] (Fig. 10.2d) showed that, depending

on the Bi/PVP ratio, nanocubes, triangular nanoplates (Fig. 10.2c), and nanospheres of bismuth could be obtained. By adding a trace amount of Fe^{3+} , nanobelts may also be produced.

Sn and In nanostructures are mostly synthesized in a similar fashion to Pb and Bi (i.e., physical vapor deposition and chemical reduction in templates or in solution) [10.43, 47, 77–79]; however, due to the very low standard reduction potential of In ($E^\circ = -0.34 \text{ V}$), stronger reduction conditions are usually needed than are applied for the other metals [10.43, 77–79].

10.1.2 Aluminum

Owing to its wide variety of beneficial properties – such as low density, high strength-to-weight ratio, ductility, electrical conductivity, and corrosion resistance – bulk-phase metallic aluminum is widely used in the packaging, transport, and construction industries, in household appliances, in electronic devices, etc. It is worth pointing out that Al is one of the most abundant elements in the Earth's crust; however, it is almost always found combined with other elements due to its high reactivity. Because of the low standard reduction potential ($E^\circ = -1.66 \text{ V}$), aluminum ions can be reduced almost only with alkali metals. In practice, electrolysis of a melt of $\text{Na}_3\text{AlF}_6\text{-Al}_2\text{O}_3\text{-CaF}_2$ (and alternatively other additives such as AlF_3 , MgF_2 , and KF) is applied for bulk production [10.81]. To date, two main types of methods have been developed for low-temperature electrochemical deposition of Al from nonaqueous solutions. For the first procedure, which was demonstrated in the 1950s [10.82], AlCl_3 together with LiAlH_4 or LiH is dissolved either in tetrahydrofuran or diethylether. In recent electrochemical deposition techniques, various ionic liquids [10.83–85] are used as solvents for aluminum chloride.

Aluminum nanostructures have been researched and used for several decades in optical coatings and in electrically conductive wiring in micro- and nanoelec-

tronics, since Al thin films are quite easy to produce by thermal evaporation [10.86, 87] and sputtering of the pure metal or by chemical vapor deposition, e.g., from Al-alkyl precursors [10.88–90]. Nanosized patterns of thin Al films are routinely obtained by e-beam lithography [10.91, 92]. A further advantage of using aluminum is the thin, self-limiting native oxide layer, which grows rapidly on exposure of the surface to ambient air. This oxide may be directly used as electrically insulating passivation, or it can be etched easily if not needed. Apart from electrical and optical devices, Al nanoparticles (NPs) have also attracted interest as a future fuel or propellant material owing to the energetic bonds that form on oxidation of Al with oxygen or halogens [10.93, 94].

Various methods to produce aluminum nanostructures have been reported lately. Mahendiran and coworkers [10.95] demonstrated synthesis of NPs of ca. 25 nm diameter from a solution of AlCl_3 and LiAlH_4 in THF using a combined electro- and sonochemical route. Foley et al. reported a chemical route, in which triethylamine alane in heptane solution is decomposed at 70°C in the presence of Ti-isopropoxide, yielding NPs with size from 50 to 500 nm [10.96]. Pulsed laser ablation of Al targets under ethanol or in vacuum – as a rather generic route to prepare various metal nanoparticles – has also been utilized to form Al NPs [10.97–99].

Template-directed techniques offer a plausible way to grow Al nanowires (NWs) too. Electrodeposition from ionic-liquid-based electrolytes [10.100, 101] and injection molding of molten Al metal [10.102] in porous templates have been reported. Aluminum nanowires can be synthesized, in a similar fashion as Zn or Sn, by employing physical vapor deposition (PVD) techniques based on vapor–solid (VS) growth mechanism [10.80, 103]. Benson and coworkers decomposed $\text{H}_3\text{AlN}(\text{CH}_3)_3$ precursor at temperatures of $125\text{--}300^\circ\text{C}$ to produce Al nanowires of 45–85 nm diameter on Ni, Cu, and steel surfaces and then used them as a large-specific-surface electrode material for supercapacitor application (Fig. 10.3) [10.80].

10.2 Transition Metals

The elements of the d-block are usually referred to as transition metals and have an incomplete outer d-shell of electrons. In a strict sense, Zn with its electron configuration $[\text{Ar}]3d^{10}4s^2$ is not a member of this group, and actually shows quite similar chemical properties to alkali-earth elements. Since most textbooks treat the

elements of the Zn group together with the transition metals, here we also discuss it along with copper and some of the refractory metals [10.24, 25, 104]. Titanium, tungsten, molybdenum, and tantalum as hard, mechanically and thermally durable materials are listed after each other in this section. Not only their physical but

also their chemical properties – stemming from their relatively low standard reduction potentials – tie these elements together.

10.2.1 Titanium

Physical vapor deposition methods are among the plausible routes to form nanosized structures of titanium. Evaporated thin films and e-beam lithography-defined patterns represent the mainstream of fabrication, and are used in generating catalyst nanoparticles, thin coatings, as well as electrical components.

Electron-beam-deposited thin (< 1 nm) titanium films have been applied as a solid precursor on a Si surface for titanium silicide nanoparticle formation. When annealing the film in H_2 at 670–900 °C, the metal diffuses into the substrate and forms a silicide phase, which is catalytically active for subsequent chemical vapor deposition (CVD) of Si nanowires [10.106].

Lehtinen and coworkers fabricated Ti nanowires (tens of micrometers long, less than 50 nm in diameter) on a Si surface using e-beam lithography followed by evaporation in ultrahigh-vacuum conditions. Low-energy ion milling was applied to decrease the diameter of the nanowires, allowing size-dependent analysis of electrical transport behavior. Experiments carried out below 1 K showed that the critical temperature for superconductivity is reduced and that broadening of the transition temperature range occurs with decreasing wire diameter. This latter effect is due to quantum fluctuations of the order parameter, which may be utilized to construct new quantum devices such as qubits and standards of electric current [10.107, 108].

Titanium is known to form strong bonds with a number of different types of solid surfaces, and thus Ti (and also W and Ta) is frequently used as an adhesion-promoter sublayer for thin films of other metals (such as Au, Pt, Cu, and Ni) to be deposited on plastics or metal oxides/nitrides [10.109]. While most of the metals directly adhere to Ti, the reason for good sticking to oxides (and some polymers) is the –OH-terminated Ti surface, which may easily form when the surface is exposed to ambient air or to traces of oxygen and water vapor in the vacuum chamber. The interaction between the hydroxyl groups of a Ti surface and, e.g., the hydroxyl, carboxyl, and amine groups of the other surface can result in H-bonding or eventually in covalent Ti–O–Me (where Me is a metal) bonds if a condensation reaction takes place, similar to those exploited in nanotransfer printing [10.110]. Carbon also seems to have a reasonably strong interaction with titanium, as

Fig. 10.4 (a) SEM and (b) TEM images of Ti nanowires synthesized on a Ti plate in 5% HCl solution at 180 °C. Inset shows a selected-area electron diffraction pattern. (After [10.105])

concluded by Zhang and Dai after studying e-beam-evaporated Ti films deposited on single-walled carbon nanotubes (SWCNT). Titanium films form thin continuous coatings, in contrast to other metals (such as Au, Pd, Fe, and Al), which tend to agglomerate to particles. The as-made Ti coating may be used as a metal nanotube with a coaxial carbon nanotube (CNT) interior, or alternatively can be applied as a buffer layer or adhesion promoter for other metals, thus enabling synthesis of multilayer structures having single-walled carbon nanotubes in their core, Ti in the mid-layer, and a tubular metal coating layer (Au, Pd, Fe, and Al) outside [10.111].

While pulsed laser ablation (PLA) of a Ti target in vacuum has been demonstrated as a potential tool for generating nanoparticles of Ti [10.112, 113], somehow PLA has not become a practical production method for metallic Ti NPs during the past years. Instead, TiO_2 nanoparticles have been synthesized by ablating a metal target submerged in water [10.114–116].

Chemical synthesis of Ti has also been demonstrated by a variety of methods. Though it was found impossible to reduce Ti^{4+} to Ti with $NaBH_4$ in ionic liquids [10.117], chemical vapor deposition from a $TiCl_4$ precursor at 640–670 °C followed by annealing in H_2 at 920 °C was sufficient to produce Ti-rich nanosized islands on Si wafers and to form $TiSi_2$ catalyst particles for subsequent Si nanowire synthesis [10.118]. Corrias and coworkers applied potassium intercalated multi-walled carbon nanotubes (MWCNTs) as templates with reducing behavior to generate α -Ti (hexagonal close-packed, hcp) nanoparticles of 2 nm size on the surfaces of CNTs from Ti isopropoxide [10.119].

A facile route to produce Ti nanowires on Ti plates was proposed by Wu and coworkers [10.105]. In their method, Ti surfaces were etched in dilute (5%) aqueous HCl solution at elevated temperature (150–200 °C) in an autoclave, resulting in the for-

mation of nanowire forests on the surface (Fig. 10.4). When decorated with Pt nanoparticles, the Ti nanowire-supported materials could be used as high specific surface area catalytic electrodes with low charge-transfer resistance ($85 \Omega/\text{cm}^2$), e.g., for oxidation of methanol [10.105].

Another interesting route to produce Ti nanowires was proposed by Huang et al. [10.121]. They used electrochemical (anodic) etching of NiTi substrates in 20% H_2SO_4 and 80% methanol solution (at 18 V for 60 s), yielding single-crystal titanium nanowires along the $\langle 110 \rangle$ directions of the substrate.

While both chemical- and electrochemical etching techniques were suitable to form Ti nanostructures on Ti or Ti-containing surfaces, attempts to obtain metallic Ti on conductive surfaces by electrodeposition seemed to fail. In their work, Endres et al. showed that metallic titanium cannot be electrodeposited from titanium halides and isopropoxide when using ionic liquids (ILs) as solvents despite the wide electrochemical window offered by the solvents. They suppose that the underlying reason is the insolubility of partially reduced nonstoichiometric halide and oxide products in the ILs [10.122].

As synthesis of truly metallic Ti nanostructures is mainly limited to low-throughput methods, applications of such structures have not really spread into daily use in commercial devices. However, once large-scale production of Ti nanoparticles or nanowires and their packaging to prevent, e.g., their oxidation become possible, a series of novel and fascinating applications may be realized according to computational studies reported lately.

First-principles total-energy calculations revealed that Ti atoms adsorbed on the surface of SWCNTs are able to bond four H_2 molecules per Ti atom because of a unique hybridization of the Ti-d, $\text{H}-\sigma^*$, and C-p orbitals. Though calculations for nanoparticles were not performed, the results suggest hydrogen storage and catalyst applications [10.3]. Molecular dynamics (MD) simulations showed that ultrathin ($d < 2 \text{ nm}$) Ti NWs have helical structure with molecule-like electronic states for diameters below 1 nm and bulk-like behavior above that [10.5]. The melting temperature of similar ultrathin Ti NWs with multishell cylindrical structures was calculated (by MD simulations) to be lower than that of the bulk metal but higher than that of nanoparticles of similar size (i. e., less than 1.2 nm in diameter). The computed smooth heat capacity versus temperature curve and the sensitivity of bond length fluctuation to temperature suggest the coexistence of liquid and solid

phases due to finite-size effects [10.4, 6]. Though bulk Ti is a paramagnetic material, deformed nanowires of Ti are predicted to show ferromagnetic ordering due to the polarization of the d-electron states [10.7, 8].

10.2.2 Tungsten

Large amounts of bulk-phase tungsten are used in hard materials such as tungsten carbide and in alloys that provide high mechanical strength and corrosion resistance. Owing to its good electrical conductivity and good wetting properties, tungsten is a component of under-metallization layers in integrated circuits (similar to titanium and molybdenum). Its high melting point and low vapor pressure at elevated temperatures allow high-temperature applications in vacuum tube filaments, heating elements, and incandescence lamps.

Interest in tungsten nanostructures has been growing steadily as they may find use in applications as pH-sensitive electrodes [10.123], atomic force microscopy probes [10.124], and field emitters [10.125, 126], and in components of nanoelectromechanical systems [10.127].

Metal nanoparticles can be obtained by reducing tungsten oxides at 500°C in H_2 [10.128], in contrast to microparticles requiring 900°C [10.129]. Nanoparticles of tungsten (with oxide shell) have also been prepared by reducing a metal complex by an organopolysilane oligomer at low temperature [10.130]. Further synthesis procedures include thermal decompo-

Fig. 10.5 Growth mechanism of tungsten nanowires by a vacuum pyrolysis carbothermal (VPC) process from a mesolamellar precursor. (After [10.120])

Fig. 10.6 Tungsten nanowires prepared by directional solidification and electrochemical processing of NiAl-W eutectic alloy. (After [10.140], courtesy of Wiley-VCH)

sition of $W(CO)_6$ [10.131, 132], sonoelectrochemical reduction from citrate complexes [10.133], e-beam-induced radiation damage of WO_3 [10.134], pulsed laser ablation of a W target in He atmosphere [10.135], ultraviolet (UV) laser-assisted chemical vapor deposition from $WF_6/H_2/Ar$ [10.136], and e-beam-induced decomposition of $W(CO)_6$ [10.137, 138]. Besides nanoparticles, only a few reports have been published on synthesis of one-dimensional tungsten nanostructures [10.120, 139–141].

In a novel method, metallic tungsten nanowires with diameters of 20–80 nm and lengths of several micrometers have been obtained in large quantities [10.120] by Li and coworkers. First, mesolamellar tungsten oxide-surfactant precursor (WO-L) was generated under mild hydrothermal conditions. Then, a vacuum pyrolysis/carbothermal (VPC) process was applied to remove the surfactant species from the lamellar inorganic-surfactant precursor. The authors proposed a new mechanism (Fig. 10.5) for the nanowire formation including four steps:

1. Evolution of cetyltrimethylammonium (CTA)– WO_4 ion pairs
2. Formation of highly ordered lamellar assemblies
3. Development of scrolls by rolling up of lamellar sheets owing to vacuum heating
4. Reduction of tungstate by pyrolytic carbon.

High-aspect-ratio single-crystalline NWs with a thin oxide layer were successfully synthesized by directional solidification and electrochemical processing of NiAl-W eutectic alloy (Fig. 10.6) [10.140] and by rapid thermal annealing of W films [10.126]. Catalytic synthesis based on a vapor–solid–solid (VSS) mechanism

route was reported by Wang and coworkers. Tungsten powder mixed and then annealed together with $NiNO_3$ was used to prepare WO_3 and $NiWO_4$, which in turn was reduced with H_2 [10.142] to obtain W nanowires as the product with Ni nanoparticles at the tip of the wires.

10.2.3 Molybdenum

Bulk molybdenum is primarily utilized in metallurgy to prepare alloys with advanced wear- and corrosion-resistance behavior. When going to the nanoscale, direct applications of Mo are very rare and limited to catalysis mainly. Though nanoparticles or clusters of this metal are relatively easy to synthesize by both chemical [10.9, 143–148] and physical [10.149–151] methods, its practical/industrial relevance – other than in catalysis – seems to be negligible compared with molybdenum oxides and sulfides, and is mainly the focus of academic research today [10.10–13].

However, molybdenum sulfides and oxides are widely studied and used, e.g., in tribology (wear and friction of surfaces) [10.152, 153], in catalysis [10.154–161], and in catalytic electrodes for supercapacitors and fuel cells [10.162–165], as well as holding promise for use in novel electrical components [10.166–168]. So far, the petrol industry has been the major user of MoS_2 catalyst nanoparticles (and their different modified derivatives) on alumina support for hydrodesulfurization (HDS) of hydrocarbons [10.154–157]. Apart from HDS, sulfides are also considered to be useful in catalyzing methanation [10.158] and in H_2 generation reactions [10.159, 160].

10.2.4 Tantalum

While nanostructures of carbides, oxides, nitrides, oxynitrides, and sulfides of tantalum are routinely synthesized by, e.g., vapor–solid reaction, chemical vapor deposition, laser ablation, surface-assisted chemical vapor transport, anodization, and sputtering, and used in superconductor, photocatalyst, and other applications, research on metallic Ta nanoparticles is rather sparse [10.169–179]. The reason is similar to that of other transition metals: it is difficult to reduce from its oxidized state, and once reduced, it is prone to oxidation under common environmental conditions. There are, however, some interesting methods to produce and utilize Ta nanostructures.

Mativetsky and coworkers have grown nanoparticles (and self-aligned chains of those along surface

Fig. 10.7a–d Tantalum nanoparticles formed on KBr 001 surface after e-beam deposition of (a,b) 0.6 and (c,d) 1.8 molecular layers. Images in panels (a–c) were acquired using non-contact-mode atomic force microscopy, while the image in panel (d) was taken by transmission electron microscopy. Arrows indicate gaps between adjacent nanoparticles nucleated at a step. (After [10.180])

steps) on single-crystal KBr by e-beam deposition (Fig. 10.7). Despite the cubic lattice of the substrate, the Ta particles form as separate islands with fractal-like shape, suggesting poor interaction between the substrate and the nanoparticles [10.180].

Nanoparticles of Ta were shown to form in a H_2/Ar arc plasma when applying bulk Ta as both anode and cathode material. Because of the high temperature, the electrodes start to melt and evaporate, leading to a vapor of metal atoms and clusters, which thermalize and coalesce through collisions, thus forming nanoparticles [10.182].

Besides the aforementioned physical methods, chemical routes may also be possible under strongly reducing conditions. Metal-graphite multilayer (MGM) structures may be obtained by intercalating metal chlorides for instance with natural or highly oriented pyrolytic graphite (NG or HOPG, respectively) followed by chemical reduction of the chloride in H_2 flow at elevated temperatures [10.183, 184]. Using a two-step procedure reported by Walter et al., first, anhydrous $TaCl_5$ is mixed with HOPG and stored in Cl_2 atmosphere at $400^\circ C$ for 4 days, then exposed to H_2 gas at $1000^\circ C$ for 1 week to prepare Ta nanoparticles in-

Fig. 10.8 TEM image of salt-encapsulated Ta nanoparticles synthesized by the sodium/halide gas-phase (flame) combustion process. (After [10.181])

tercalated with the graphene layers in graphite. The as-obtained structures behave as superconductors similar to tantalum carbide. As suggested by Suzuki and coworkers, the Ta nanoparticles act as localized spins, which can couple with the adjacent layers separated by the graphitic layers [10.184].

Axelbaum and colleagues developed and patented a technology capable of producing large volumes of nanopowders of metals as well as their composites by reacting sodium vapor with gas-phase metal chlorides in a flame [10.181, 185] (Fig. 10.8). At high temperatures, Na vapor reduces metal (such as Ta, Ti, Al, Nb, Si, W, or Fe) chlorides (or other halides) and produces metal nanoparticles. By controlling the temperature and heat losses in the reactor, condensation of the byproduct NaCl vapor on the metal nanoparticles can be regulated. Increased temperature favors sublimation of the salt and consequently the formation of larger metal nanoparticle cores, while lower temperatures result in condensation of the salt vapor on the core. The as-formed shell acts as a barrier coating, protecting the metal core from moisture and air. The salt encapsulation can be removed, for instance, by vacuum sublimation, thus releasing the Ta nanoparticles for their end use.

10.2.5 Zinc

Zinc is an industrially important metal applied in large quantities in batteries, anticorrosion coatings, and various structural alloys today. Most of the studies related to elemental zinc are focused on the generation of zinc

Fig. 10.9 Low- (a) and high-magnification (b) SEM images of Zn nanobelts. (After [10.190])

chalcogenide nanostructures due to their semiconducting and piezo- and pyroelectric properties, which find applications in pigments and (photo)catalytic processes, and thus are widely studied in the contemporary literature [10.186–189].

Vapor–solid (VS) growth of Zn nanowires has been reported by several groups. In this method, a vapor of Zn is generated first under protective gas, by either evaporating pure metal [10.191] or decomposing organic zinc compounds [10.192], or by reacting ZnO or ZnS with carbon, ammonia, H₂, etc. at elevated temperature [10.190, 193, 194]. When the vapor of Zn enters a colder zone of the reactor (typically a two-zone furnace is employed), condensation of the vapor starts and Zn nanowires are observed to grow. Since the process is not catalyzed by any separate nanoparticle or seed, it is referred to as VS growth [10.191]. To produce nanoparticles, PLA has been applied [10.195, 196]. Most of these studies, however, agree that Zn nanostructures are covered by a thin layer of ZnO [10.191, 193, 195] (Fig. 10.9a,b).

Solution-phase synthesis of Zn nanomaterials has not been widely explored, since the procedure has to be conducted under inert gas protection to avoid oxidation. Electrochemical deposition as one of the major synthesis tools for metallic zinc has been successfully utilized to prepare both single- and polycrystalline nanowires with diameter of 40–100 nm in porous AAO and PTCE membranes [10.197].

10.2.6 Copper

In everyday life, copper is used for several kinds of applications and devices. One major advantage of copper, compared with other metals, is its excellent electrical conductivity, which is greater than that of any other metal apart from silver. Most copper is used in electrical wires for motors, transformers, cars, integrated circuits, etc. to transfer electrical energy in an efficient manner with minimal environmental impact. Copper is also widely used in heat exchangers and heat sinks due to its high thermal conductivity. Other attractive proper-

ties of this metal are its durability, corrosion resistance, and antimicrobial effect, which enable a vast number of applications in the construction industry as a structural and alloying material, and as a functional surface coating.

Most probably, catalysis and electronics are the two main fields that could greatly benefit from the availability of copper nanostructures. In the last decades, copper nanostructures with various morphologies and oxidation states have been widely studied for applications in heterogeneous catalysis [10.198–200]. Furthermore, the surface chemistry on Cu has also been elaborated in detail by Somorjai et al. [10.201]. Copper, particularly in nanoparticle form [10.202], has found use as a catalyst in water–gas shift reactions [10.200, 203, 204], methanol synthesis [10.205–207], aryl homocoupling [10.208], growth of Si nanowires by chemical vapor deposition (CVD) [10.209], etc.

One of the very first methods for preparation of Cu nanowires (which were encapsulated in carbon nanotubes) was demonstrated by Setlur et al. in a hydrogen arc between a graphite cathode and a graphite–copper anode [10.210]. Evaporation and subsequent condensation of Cu, forming nanorods and nanowires at 10^{−4} Pa pressure in a transmission electron microscope (TEM) column, was reported by Liu and Bando [10.211]. Though several other physical methods such as laser ablation [10.212, 213], pulsed wire discharge [10.214], and evaporation [10.215] exist, because of their limited production volume and associated price, the aforementioned physical methods are surpassed by the chemical ones, since a number of different reaction routes enable the production of nanoparticles of different sizes and shapes, even in a simple beaker under mild conditions [10.216–228]. The key to obtaining various crystal shapes is the presence of surface-capping agents (to selectively adsorb onto and block specific crystal planes) [10.17, 229] or addition of ionic impurities [10.69, 225].

Hexagonal nanoplates of copper have been prepared by reduction of Cu(CH₃COO)₂ with hydrazine hydrate in acetonitrile [10.226]. Nanoparticles of cubic, tetrahedral, and rod shapes with size ranging from 5 to 25 nm were obtained by reduction of copper acetylacetonate with 1,2-hexadecanethiol in octyl ether in the presence of oleyl amine and oleic acid serving as capping molecules [10.227]. Cu nanowires with diameter of ca. 85 nm were prepared by a complex-surfactant-assisted hydrothermal route from Cu(II)–glycerol complexes reduced by phosphite in the presence of sodium dodecyl benzenesulfonate (SDBS) [10.221]. Recently,

Fig. 10.10 (a) SEM image of Cu nanowires prepared by a hydrothermal process in the presence of hexadecylamine (HDA). (b) SEM image of Cu nanocubes. (After [10.220])

we reported a very rapid route to ultralong copper nanowires (Fig. 10.10a) and nanocubes (Fig. 10.10b) on a large scale with HDA as capping agent [10.220]. In a typical synthesis, CuCl_2 and glucose were dissolved in water, followed by addition of hexadecylamine (HDA). After stirring for several hours, the light-blue solution was placed in an autoclave that was heated to 120°C . In a recent study, this method was slightly modified by Jin and coworkers to produce single-crystal Cu nanowires [10.230]. In a similar hydrothermal route, polycrystalline and single-crystalline Cu nanowires were generated in the presence of octadecylamine [10.231]. Though copper has a positive standard electrode potential ($E^\circ = 0.34\text{ V}$) it is still rather easy to oxidize its surface, or even the entire volume of the material if it is nanostructured. For

Fig. 10.11 CuPd bimetallic nanotubes prepared by galvanic exchange reaction on Cu nanowires. (After [10.232])

instance, exposing Cu nanowires to solvated cations of noble metals (Pt^{2+} or Pd^{2+}) can initiate galvanic replacement reactions, in which the nanowires undergo oxidation and dissolution while the precious metal is depositing on the surface of copper thus forming nanotubes of CuPt or CuPd alloys [10.232] (Fig. 10.11).

It is worth mentioning that Cu nanostructures are prone to oxidation. Even trace amounts of oxygen dissolved in the solution of reactants can cause partial oxidation, causing sometimes controversial results, thus it still remains a great challenge to synthesize pure copper particles by solution-phase methods [10.69, 233–235]. One way to protect Cu seeds from oxidation during production is to apply a N_2 atmosphere and to purge the reaction solution with inert gases.

10.3 Concluding Remarks

In this chapter, we have provided an overview on nanostructures of metals excluding ferromagnetic and precious ones, which are described in Chap. 9. As most of the metals belong to this category, we organized them based on the following criteria:

1. Reasonable chemical stability under ordinary conditions
2. Abundance of raw materials
3. Industrial importance in bulk form.

As it turns out from the literature review, this particular field of materials science has not yet been fully explored. Some potential applications of the metal

nanostructures are discussed in the cited literature. However, despite numerous reports on laboratory-scale synthesis, controlled bulk production and utilization of such nanostructures are still in the early stage of technical development and should be improved. Since the majority of these elements are prone to oxidation, difficulties related to chemical stability need to be studied and should be solved by surface engineering; otherwise nanostructures made of compounds of these metals are expected as a result. Besides the existing knowledge, further peculiarities of these materials at the nanoscale remain to be revealed to enable their wide use in novel technologies and devices.

Alloys on the Nanoscale

Giovanni Barcaro, Alfredo Caro, Alessandro Fortunelli

An overview is provided of nanostructured alloy materials as both isolated particles with nanoscale diameter (nanoalloys) and bulk materials with nanoscale structure. The methods for preparing and characterizing these systems from both experimental and theoretical modeling points of view are presented, and the basic knowledge on their structural, catalytic, mechanical, optical, and magnetic properties is reviewed. It is shown that, due to the increased freedom associated with composition and chemical ordering, new physical phenomena appear in metal multicomponent nanosystems, as well as novel or profoundly modified properties: For example, new structural motifs can arise depending on the structural and energetic characteristics of the metal components, and the size of the system. Hence, the catalytic activity, mechanical strength, plasmonic and nonlinear optical, as well as magnetic responses exhibit features in multicomponent nanostructured systems which are different and can in principle be finely tuned with respect to their pure counterparts. The challenges associated with full exploitation of these possibilities are outlined.

The chapter starts by defining some concepts and principles specific to the field of nanoalloys which are then used in the next sections (Sect. 11.1). A brief overview of the methods for preparing (Sect. 11.2) and characterizing (Sect. 11.3) nanostructured alloys then follows. The core of the chapter (Sect. 11.4) presents a discussion of the properties of these materials, distinguished into: structural, catalytic, optical, and magnetic. Section 11.5 is devoted to nanostructured bulk alloys. A brief section on applications (Sect. 11.6) and an outlook (Sect. 11.7) conclude the chapter.

Metal nanoclusters and nanoalloys (i. e., pure or mixed metallic aggregates of dimensions ranging between 1 and 100 nm) are a subject of great interest in basic science as well as in current technology, where they find many applications (and many more promising ones have been prospected in the literature) due to their unique properties: from chemical sensing (artificial noses) to heterogeneous catalysis [11.1, 2], from magnetic recording to optoelectronic devices, thermal treatment of cancer, and *cell imaging*, i. e., colorimetric probes for DNA detection [11.3–6].

In a wide historical perspective, all this may be thought to stem from metallurgy thousands of years ago, when humanity unknowingly discovered how to produce metal nanoparticles and to exploit their surface plasmonic resonance, i. e., the coherent and collective oscillation of electrons involved in metallic bonds in confined systems subjected to electromagnetic radiation of proper wavelength, for esthetic purposes (stained glass and fine glassware, with coloring durable till today) [11.7]. Materials containing metal nanoparticles were also proposed for curative use [11.7] in what can be considered as a forerunner of nanomedicine. A more conscious step forward was achieved in the mid-19th century by *Michael Faraday*, with the preparation of colloidal suspensions via chemical reduction of metal salts in the presence of stabilizing agents in solution [11.8] and the study of their optical properties. The physics of nanoscale metal clusters then strongly developed in the 20th century with the advent of nanocatalysis and dramatically in recent years, following the continuous advances in synthetic and characterization tools that allow manipulation of matter at the nanometer scale by preparing and measuring the properties of nanostructured systems with increasing precision [11.9–14] and the development of theoretical methods able to rationalize and predict experimental behavior and properties [11.15–18].

The fundamental reasons for the interest in metal nanosystems and their fascinating applications ultimately lie in the peculiar features of confined metallic bonds [11.19, 20]. The presence of conduction-band electrons whose mobility enhances transport and response properties [11.21] confined within a finite space, combined in transition metals with localized electrons in incomplete d-shells, assuring both easy formation and breaking of chemical bonds (and thus a rich and varied chemistry) and large magnetic moments, and the sensitivity of these properties to coupling with size, shape, composition, and external fields, make metal nanoparticles and nanoalloys truly unique materials, an

ideal topic of research and investigation in many fields of science and technology.

In particular, combining nanostructured metal systems or metal nanodots with alloying results in a class of systems of great interest in terms of both basic and applied science: alloyed (multicomponent) metal nanoparticles or nanoalloys [11.22–25] (Fig. 11.1), which are the subject of the present chapter.

There are a number of reasons why a gain can be achieved by employing a multicomponent nanostructured system with respect to pure and/or extended systems and which justify the importance of nanostructured alloys in the field of metal nanoparticles and in the general field of nanomaterials. First, new structural motifs with respect to pure systems can be created by alloying, thus generating novel structure–property relationships. Second, the chemical and physical properties of a particle can be tuned by varying not only the size and shape but also the composition (i. e., the ratio between the different chemical species within the particle) and the degree of atomic mixing or chemical ordering or compositional structure (i. e., the distribution of the different atomic species in the structural framework): For example, the surface chemistry of a particle and its interaction with the environment can be modified by coating with an overlayer of a different material, or additional functionalities can be added to change its recognition capabilities. All this is very important as it allows one to finely modulate the physics of the metal–metal interactions and consequently to tune the properties of these systems nearly at will. This same freedom, however, especially that associated with chemical ordering, also represents a challenge in terms of both experimental realizations and theoretical predictions. In particular, a high degree of precision is required in the synthesis protocols to achieve control over chemical ordering in nanoalloys, and – once achieved – the corresponding link to properties must be clarified. This is not easy, as only recently have characterization techniques been developed that allow one to obtain accurate information on the structural properties of these materials; see [11.26–29] and Sect. 11.3. In the cases in which this has been possible it has been shown that chemical ordering can be crucial in determining the system properties. Ag–Pt particles, for example, exhibit a different optical response depending on whether they are core–shell or random solutions [11.30]. Mechanical properties are equally known to be strongly affected by surface segregation [11.31]. The precise arrangement of the species in the particle is also important in catalysis, being dominated by processes occurring at surface or

Fig. 11.1 Definition of nanoalloys

11.1 Concepts and Principles

In this section we briefly discuss some of the concepts and methods that are peculiar to the field of nanostructured alloys, especially at the theoretical level. An excellent introduction to the field of nanoalloys can be found in [11.25].

The first issue that one encounters in dealing with nanoalloys is how to compare the stability of nanoalloys of different chemical composition. In this context, a very useful concept is that of mixing energy. Suppose that one has alloy nanoparticles all of a given size (i. e., the same number of atoms) but different chemical composition and suppose that one knows the energy of each one of them; then, which quantity can one define to compare their energies and single out the most stable one? One possibility is the mixing energy, defined as

$$\Delta[N_A, N_B] = E_{\text{alloy}}[N_A, N_B] - N_A E_A[N]/N - N_B E_B[N]/N,$$

where $E_{\text{alloy}}[N_A, N_B]$ is the energy of a nanoalloy cluster composed of N_A atoms of species A and N_B atoms of species B, $N = N_A + N_B$ is the total number of atoms in the cluster, $E_A[N]$ is the energy of a pure cluster of N atoms of species A, and $E_B[N]$ is the corresponding quantity for species B (it is assumed that these are global minimum energies, i. e., the lowest energies among all possible isomers); $\Delta[N_A, N_B]$ is the mixing energy of the given nanoalloy at a specific composition, i. e., the energy released by mixing N_A A-type clusters and N_B B-type clusters all of size N

subsurface shells, and changes in the segregation pattern under operating conditions have been observed [11.32]. In short, novel phenomena or novel metamorphoses of old phenomena should be expected and are indeed encountered in this field, as the following sections attempt to show.

Moreover, by enlarging the perspective, one encounters other materials that are not usually classified as nanoalloys but that share with them most of the basic knowledge, namely nanostructured bulk alloys. In general, alloyed nanostructures can then be distinguished as: (a) isolated particles with nanoscale size, and (b) bulk materials with nanoscale structure. Section 11.5 is therefore devoted to these latter materials and their peculiar mechanical properties.

to produce N alloyed clusters of size N with composition (N_A, N_B) , divided by N . The quantity $\Delta[N_A, N_B]$ provides a measure of how thermodynamically favorable alloying is at the given size and composition. Its definition represents the natural generalization of the corresponding concept used for bulk alloys [11.24, 33].

Another complication connected with the theoretical computational description of nanoalloys is the *match* among the energy scales of the different elements composing the alloy and the crucial need to describe this accurately to achieve reliable predictions. This feature, i. e., the presence of multiple length and energy scales, is common to all multifunctional or composite systems. To provide a simple example, if a given approach calculates the ratios between the surface energies of a given element accurately, this is sufficient to correctly predict the shape of a pure nanoparticle of this element (see the Wulff construction in Sect. 11.4.1), but this is no longer true for mixed systems if the scaling factors differ for the different elements. In such a case, an absolute accuracy (or at least a homogeneous inaccuracy) should be aimed for, which is more difficult to achieve than simple relative accuracy.

The crux of theoretical and experimental research on nanoalloys is truly connected with the degree of atomic mixing or chemical ordering or compositional structure of the particles (i. e., the distribution of the different atomic species in the structural framework). The problem at the experimental level is that, while it is in principle not too difficult to control composition, it

Fig. 11.2a–c Orbit structure of selected even-numbered truncated octahedra: (a) 6-atom TO(2,0); (b) 38-atom TO(4,1), obtained by adding 32 atoms to (a); (c) 116-atom TO(6,2), obtained by adding 78 atoms to (b). Different symmetry orbits are singled out by different colors and numbers. (After [11.36] with permission of ACS)

is instead much more awkward to precisely control the chemical ordering of a nanoparticle, and invasive post-preparation treatments are often necessary to equilibrate this variable. The point is that chemical ordering greatly increases the degrees of freedom of the system, for example, the number of different possible realizations of a nanoalloy of given size, structure, and composition. Just to give a rough idea, it can be observed that, neglecting the reduction due to point group symmetry, for a cluster with given structure and N atoms, of which N_A are of species A and N_B are of species B, one has $(N_{\text{tot}})!/((N_A)!(N_B)!)$ possible different *homotops*, i. e., isomers sharing the same skeletal structure and composition but differing in the mixing pattern [11.23]. This is a number which increases exponentially with the size of the system, rapidly becoming impossible to sample or explore even using computationally inexpensive theoretical approaches. Even the simple description of which phases of chemical ordering are realized is non-trivial. Order parameters associated with chemical order have been defined to distinguish the various ordered phases of bulk alloys [11.34] but have seldom been used so far for nanoalloys [11.35].

At the theoretical level, a viable procedure to search for the equilibrium configurations of the system is to start from a random arrangement and to consider moves based on an exchange of the coordinates of two atomic species, as realized in the exchange-only basin-hopping algorithm [11.37]. An alternative and more effective solution is to consider structurally magic clusters. In this approach [11.24] attention is focused on configurations exhibiting structural shell closure and thus as a norm a high point-group symmetry, which is exploited to partition the atoms into symmetry *orbits*, i. e., group of atoms equivalent by symmetry (transformed into

one another by the operation of the symmetry group) (Fig. 11.2). As a consequence, the degrees of freedom of the system are reduced from the number of atoms N to the number of symmetry-nonequivalent orbits N_{orb} , and correspondingly the number of distinct homotops is exponentially decreased, making theoretical simulations feasible even at the first-principles level for medium-sized particles: For example, the segregation patterns of PdPt nanoparticles were recently studied [11.36], finding that the interplay of metal–metal homo- and heterointeractions produces an unusual Pt surface segregation in Pd-rich particles (in spite of the larger Pt bulk energy) and a novel patchy multishell pattern around the equimolar composition in which each shell is decorated by *patches* of like atoms; see the discussion in Sect. 11.4.1. The use of magic clusters is also very useful for studying properties (see, e.g., the Sects. 11.4.3 and 11.4.4 on optical and magnetic properties), both to reduce the computational effort associated with a single computation and to reduce the number of homotops to be considered (Sect. 11.4.1).

In this connection it can be added that another very efficient tool to drastically reduce the computational effort and to enlarge the scope of systems amenable to first-principles simulations is based on the use of periodic models [11.38]. Instead of studying a zero-dimensional (0-D) nanodot, in fact, one can consider a one-dimensional (1-D) or *wire* model, as depicted in Fig. 11.3. In this figure, the correspondence between a truncated octahedral 0-D cluster, supported on a square-symmetry oxide surface, to a 1-D wire in which the section of the cluster is replicated ad infinitum, is clearly shown. As in the case of magic clusters, in this approach one exploits symmetry (in this case, periodic symmetry) to strongly reduce the number of nonequivalent atoms (in this case, those contained in the unit cell). In Fig. 11.3, the indexes defining the level of truncation of the wire corners are also shown. The simplifications assured by the use of wire models in terms of reduction of the number of atoms in the unit cell and also of the degrees of freedom of the system are apparent. Through the use of such models, a 1-D system with a unit cell of 110–120 atoms can be constructed to resemble or mimic 0-D particles with 7–8 times this number of atoms, which would be otherwise extremely expensive or hardly affordable at the first-principles level with present computational facilities. This approach has been used in several instances; see, e.g., the discussion in Sect. 11.4.4 of magnetic properties later in connection with interface effects on the magnetism of CoPt particles supported on MgO(100) [11.39].

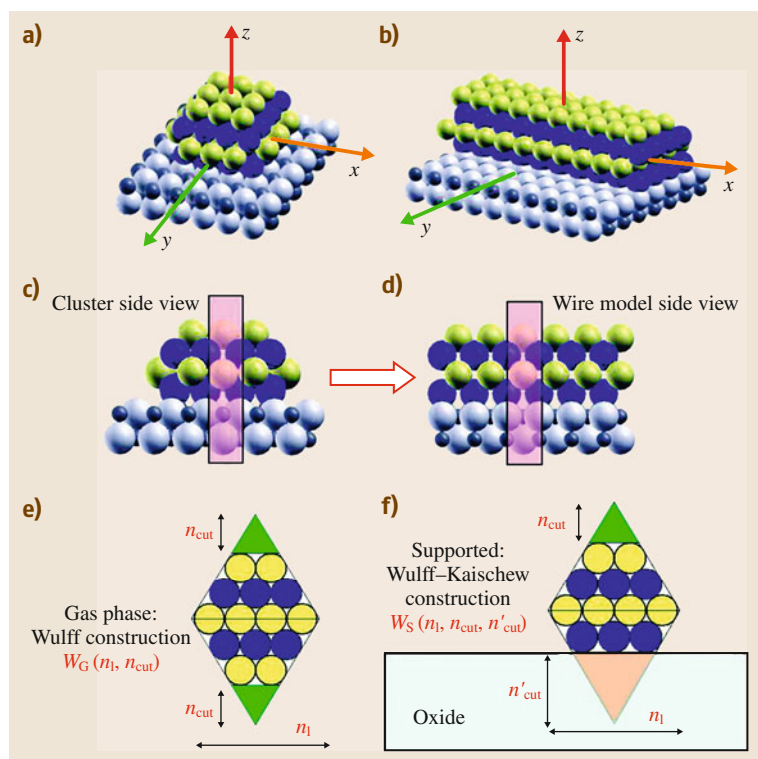

Fig. 11.3a–f One-dimensional (wire) modeling of supported binary particles. A 0-D particle **(a)** and a side view with its cross-section **(c)** are shown, together with a piece of the corresponding 1-D wire model **(b)** and a side view with its cross-section **(d)**. The Cartesian axes are also indicated in **(a,b)**. Side views are along y-axis. The truncations of a free **(e)** and supported **(f)** wire viewed along the x-axis are also shown, defining the quantities n_1 , n_{cut} , and n'_{cut} , respectively. (After [11.39] with permission of ACS)

11.2 Preparation and Synthesis

In this section we discuss some of the main experimental procedures utilized in the synthesis of nanoalloy particles. Nanostructured bulk alloys are treated in Sect. 11.5.

Roughly categorizing, the techniques used to produce alloy nanoparticles can be distinguished into two main groups: homogeneous (Sect. 11.2.1) and heterogeneous (Sect. 11.2.2). In the former class one typically finds approaches which pass through chemical synthesis in solution phase; in the latter, those relying on chemical and/or physical vapor deposition of precursors onto a support surface.

11.2.1 Solution-Phase Methods

The array of methods and techniques developed in the past to produce nanoalloys in the homogeneous phase is really endless. Limitations in both space and specific expertise hinder us from attempting a comprehensive treatment. Rather, we refer to recent excellent reviews

for a discussion of the issues and opportunities in this field [11.4, 40–45], limiting the following presentation to some general ideas and information that can help orient the reader in the vast literature on this subject, with particular attention to *hybrid* or multicomponent nanostructures [11.44].

To start with, let us recall some very basic concepts of the chemical routes for preparing metallic nanoparticles in colloidal form [11.4]. As in the pioneering work by Michael Faraday, this is most often achieved via reduction of metal salts in solution by a reductant, e.g., sodium borohydride [11.46], or alternatively via thermal decomposition of an organometallic precursor. In these homogeneous-phase methods, one usually starts from a supersaturated solution obtained either by directly dissolving the solute at higher temperature and then cooling down to low temperatures or by adding an excess of reactants. The solution must be supersaturated to make the aggregated phase (the nanoparticles) thermodynamically favored. The precipitation process

Table 11.1 Summary of the shapes, LSPR absorption peaks, demonstrated applications, and methods for synthesis of Ag nanostructures discussed in [11.43]. (After [11.43] with permission of ACS)

Shape	Illustration	LSPR	Applications	Method of synthesis
Sphere and quasisphere		320–450	SERS; LSPR sensing; assembly	Polyol process (single-crystal); Citrate reduction (quasisphere)
Cube and truncated cube		400–480	SERS; LSPR sensing; assembly	Polyol process; seed-mediated growth
Tetrahedron and truncated tetrahedron		350–450	SERS	Polyol process. light-mediated growth
Octahedron and truncated octahedron		400–500	Assembly	Polyol process; seed-mediated growth; light-mediated growth
Bar		350–900	SERS	Polyol process
Spheroid		350–900	SERS	Polyol process
Right bipyramid		500–700	–	Polyol process
Beam		–	Electron transport	Polyol process
Decahedron		350–450	–	Seed-mediated growth; light-mediated growth; citrate reduction
Wire and rod		380–460	Waveguiding; electronics; SERS; assembly	Seed-mediated growth
Polygonal plates and disc		350–1000	SERS; LSPR sensing	Light-mediated growth; polyol process
Branched structures		400–1100	SERS	Seed-mediated growth
Hollow structures		380–800	SERS; LSPR sensing	Template-directed growth

then has to overcome a thermodynamic energy barrier and thus basically consists of a nucleation step followed by a particle growth stage. In this homogeneous nucleation mechanism, a critical size exists such that clusters smaller than this size will dissolve whereas larger clusters will grow [11.4, 42]. Achieving a small size dispersion (ideally monodispersity) is one important goal [11.42], usually sought by separating as much

as possible the nucleation and growth stages [11.47]. In the heterogeneous nucleation mechanism, instead, an external seed is provided, around which aggregation of metal atoms is promoted [11.43, 48–52], which is a different, highly controllable way of separating the nucleation and growth stages. Through all these approaches, a huge variety of different morphologies have been obtained in practice, sometimes with exquisite

control over the shape and also the size of the resulting nanostructures. To show some examples, we report in Table 11.1 an overview of the different shapes in which Ag nanostructures have been modeled, taken from a recent review [11.43].

As underlined above, nanoparticles are metastable phases, tending toward the thermodynamically stable bulk phases if not hindered by, e.g., a surfactant layer which acts as a stabilizing barrier, and a large variety of different surfactant molecules and their effects on the growth have been studied in the literature [11.53]. Monodispersity can be also achieved via post facto treatments, i. e., by separating particles of specific sizes. This has been especially effective in producing very small metal particles at *magic* sizes by exploiting the higher chemical stability of metal clusters with specific numbers of atoms [11.6, 54–59]. Apart from operating on the kinetic parameters of the preparation conditions (which can lead to very effective results [11.60]), another way to orient the growth of colloidal particles is via the use of templates. This path has been thoroughly reviewed recently [11.45], so we do not discuss it in detail. One important example in this field is the use of reverse micelles as confined nanoreactors [11.12].

The problem becomes much more complicated when a multicomponent nanosystem is targeted.

Some synthetic methods are based on simultaneous growth of two (or more) components.

Coprecipitation is a common approach in this class, in which solution conditions are chosen in such a way that both elements can precipitate simultaneously and – ideally – on top of one another [11.61]. A problem in this approach is that the metal with lower redox potential is prone to be reduced before the other metal(s). This is usually avoided by using a very strong reductant to accelerate reaction so much that simultaneity is practically achieved. Still, care must be taken to avoid precipitation of the two elements as separate nanoparticles [11.62, 63]. The composition can be modulated by changing the molar ratio of the two precursors.

In other methods the growth of the two elements is separated in time.

One example is deposition precipitation or surface growth [11.45, 64, 65]. This is a two-step procedure in which nanoparticles composed of one element are first produced, ideally with a narrow particle size distribution [11.4, 41, 42], followed by a change in the reaction environment so that a second element is deposited onto the surface of the previously produced nanoparticles. In this approach the already existing surface favors hetero-

geneous nucleation on the particle surface with respect to homogeneous nucleation of the second element in the solution phase [11.66], while the mutated reaction conditions should disfavor homogeneous nucleation of the first element, thus producing a composite system. The size, morphology, and faceting of the nanoparticles used as seeds are important in determining the success and the features of the resulting systems [11.67]. Smaller seeds are more active than larger ones, and regions with higher radius of curvature will typically grow faster than smoother regions. This can be true also for some facets with respect to other ones, giving rise to preferential growth along specific directions. External influences such as light or heat can also be used to accelerate or control the process [11.45]. In particular, exploiting electromagnetic field enhancement at the surface of the underlying core facilitates the reduction of the second element, thus producing high yields and shape control [11.68] so that prisms, tetrahedra, decahedra, etc. can be obtained. The as-prepared alloy nanoparticles can naturally be in a metastable phase or configuration, in which case they will evolve in time depending on the kinetics of atomic or vacancy diffusion.

A second example is galvanic replacement [11.43, 69, 70]. Here, one starts from a given nanoparticle composed of an element A (A_s) and incorporates atoms of a second element B initially as a solvated ions (B_{aq}^{m+}) by reducing them into B_s at the expense of some A_s atoms, which are oxidized into A_{aq}^{n+}

Clearly, a prerequisite for this reaction to proceed is that the standard reduction potential of the B_{aq}^{m+}/B_s pair must be higher than that of the A_{aq}^{n+}/A_s pair, which poses constraints on the application of this technique. Second, if $n \neq m$, the different stoichiometry of the two species will generate vacancies and porosity within the particle [11.71], which may then evolve with time. Third, by playing with the mobility and concentration of the different species, it has been shown that it is possible to precisely control the final morphology and in part the chemical ordering of the resulting particles [11.43, 69, 70, 72–77].

Note that we do not discuss explicitly polymer-protected composite nanoparticles, whose preparation is partly similar to what has been described so far [11.78, 79].

Moreover, so far we have mainly discussed the synthesis of individual nanoparticles, without hinting at

the possibility of supra-organizing the particles to obtain 1-D, two-dimensional (2-D), and three-dimensional (3-D) arrays [11.43, 80, 81], which are very important, e.g., in optical or microelectronic applications. In this context, an interesting concept is that of mixing two different types of colloidal nanoparticles to achieve a supra-organized ensemble in which both species co-exist [11.82]. All this lies outside the scope of this presentation.

11.2.2 Surface Deposition Methods

Technical heterogeneous catalysts are usually produced by wet impregnation from solution [11.2, 83, 84]. In contrast, in basic or academic research, *cleaner* (more controllable) preparation methods are often employed, and chemical vapor deposition (CVD) or physical vapor deposition (PVD) are both processes which are used to grow metal particles on top of a surface. In the former, the precursor metal atoms or clusters are protected by ligands which are eliminated usually via pyrolysis (the vaporized precursors are introduced into a CVD reactor and adsorb onto a substance held at an elevated temperature, where they decompose to produce metal species), whereas the latter involves condensation from the vapor phase of the bare precursor in the form of atoms or clusters, which are deposited onto a surface where nucleation and growth take place (Fig. 11.4). Various techniques can be adopted in surface deposition methods to obtain alloyed rather than pure nanoparticles: For example, one can use a metal alloy as a vaporization source instead of a pure metal, or use two different vaporization sources, either simultaneously or sequentially, the latter procedure being especially useful to produce core-shell or multishell particles. Among the possible supports, traditionally very relevant ones are oxide surfaces for their importance in the field of heterogeneous catalysis [11.2].

From the point of view of basic research, the interest in surface-deposited metal nanoclusters and nanoalloys has translated into a series of fundamental studies in surface science in which complicated real-world systems are replaced by model systems, ideally under the most well-controlled conditions [11.85]. Two model systems are possible and have been used in the literature. In the former, extended surfaces of pure or alloyed metals are used as models of nanoparticle facets [11.86–88]. In the latter, metal nanoparticles and nanoalloys rather than extended systems were grown, typically on oxide substrates [11.85, 86, 89–91]. Excellent introductions to the field of

Fig. 11.4 Surface processes in physical vapor deposition of metal species and growth of nanoparticles

metal nanoparticles deposited on model oxide supports from the point of view of surface science are available in the literature [11.89, 90], to which we refer for more detailed discussion. In these latter surface science studies of metal nanoparticles on oxide substrates, two major simplifications are usually adopted: (a) the chosen support is a single-crystal surface – possibly with highly controlled defectivity – instead of a complicated, amorphous one as in many applications, and (b) vaporization, deposition, and growth are often achieved in ultrahigh-vacuum (UHV) conditions (i.e., at pressure below 10^{-10} mbar) instead of at atmospheric or even higher pressures. A single-crystal surface is chosen as it allows one to employ space-integrated surface science techniques (see the next section). UHV conditions ensure that each surface atom is hit by residual gas species with extremely low frequency (much less than once per hour). The aim of these studies is to derive rigorous knowledge on model systems that can shed light on the basic mechanisms underlying the complex phenomena occurring in real-world systems, and indeed a wealth of information has been derived from these efforts [11.89, 90]. Characterizing and orienting the structure of the particles and their epitaxy to the substrate are naturally fundamental steps to achieve this goal [11.91] (see Sect. 11.4.1 on structural properties). In this respect, it is worthwhile underlining that substrate preparation is crucial to achieve a thorough understanding of the phenomena at play [11.92]. An interesting analogy can also be drawn with the previous subsection, as the template-directed preparation methods discussed in the context of colloidal nanoparticles find here a counterpart in the surface-directed growth or surface nanopatterning [11.93, 94], i.e., the possibility of producing a substrate exhibiting a regular array of defects that act as (heterogeneous) nucleation centers for the metal nanoparticles or nanoalloys [11.95]. When such a templating substrate is adopted, the growing

species spontaneously self-assemble into long-range-ordered arrays of nanoparticles with reproducible size and structure over macroscopic sample areas, providing the opportunity to investigate at a fundamental level the collective functionalities originating from the ensemble behavior of the particles (Sect. 11.4.3).

Despite the importance of and the fundamental insight gained from these studies, the huge difference in experimental conditions poses the issue of the so-called *pressure and materials gaps* [11.96, 97], i. e., the ther-

modynamic and kinetic effects of reducing the pressure by orders of magnitude, e.g., on the system composition and mass transport phenomena, and the effect of considering extended surfaces instead of nanoparticles in the studies in which this further simplification is adopted. A line of current research is therefore aimed at developing characterization tools that can be used under environmental conditions, such as spectroscopic (see, e.g., [11.98, 99]) or microscopy techniques [11.100] (Sect. 11.3).

11.3 Characterization of Nanoparticles and Nanoalloys

The properties of an alloyed nanoparticle depend sensitively on the microscopic details of its structure and surroundings. To characterize these, one common way consists in adsorbing the particle on a proper support and using the tools of surface science. The major ones are described in this section. Note that a few techniques, such as high-resolution transmission electron microscopy (HR-TEM) and x-ray photoelectron spectroscopy (XPS), are also able to discriminate between the two elements forming the alloy.

11.3.1 Scanning Force Microscopy (SFM)

SFM is a suitable tool to study in situ the morphology of supported nanoparticles both under UHV and under not too large pressure [11.101]. Atomic resolution of both the nanoparticle and the insulating support can in principle be achieved. SFM is based on detection of the change in frequency (detuning) of an oscillating cantilever due to the interaction of the microscope tip at the end of the cantilever with the investigated system (Fig. 11.5).

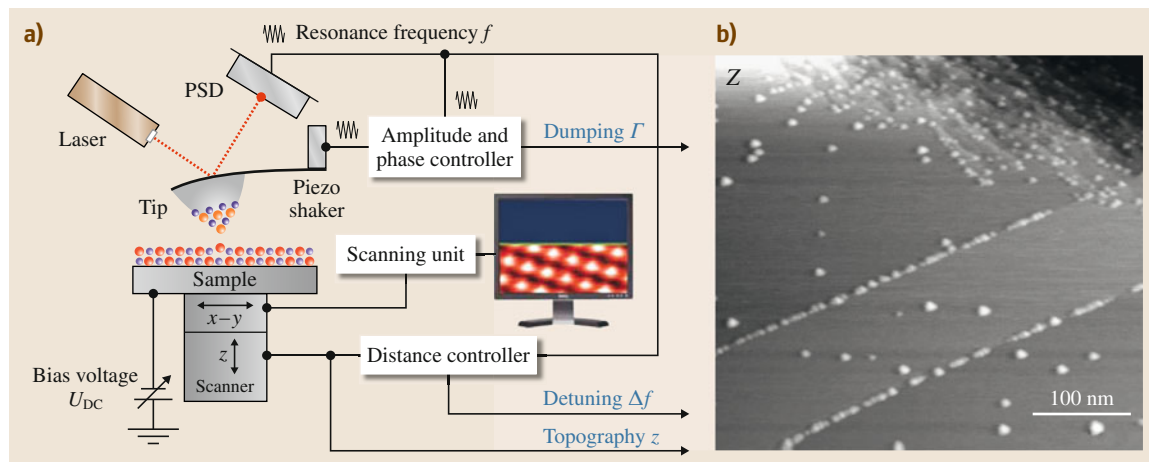

Fig. 11.5 (a) Schematic setup of a frequency-modulation noncontact AFM (nc-AFM), consisting of two independent regulation loops. The amplitude/phase controller keeps the amplitude of the cantilever oscillation constant, whereas the distance controller adjusts the tip-surface distance by keeping the detuning Δf at a constant value. The damping or dissipation output reflects the energy required to maintain a constant amplitude of the cantilever oscillation, and can also be used as an imaging signal. Note that the drawing is only a simplified diagram of the function principle (PSD: photo signal detector). (After [11.101]). (b) Topography image of the KBr(001) surface after deposition of 0.07 monolayers (ML) of gold. Note that the density of clusters directly scales with the density of steps, which is lower in the *lower part* of the image than in the region at the *top of the image* ($400 \times 400 \text{ nm}^2$, 293.2 kHz tip, $\Delta f = -23.9 \text{ Hz}$, $k = 48 \text{ N/m}$, $A_{p-p} = 13 \text{ nm}$, $U_{DC} = 5.0 \text{ V}$, contrast in $z = 6 \text{ nm}$). (After [11.102] with permission of APS)

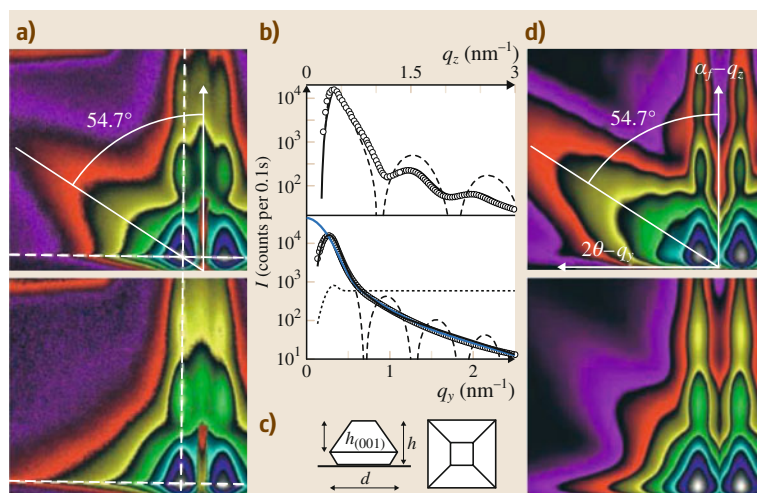

Fig. 11.6 (a) 1.5 nm-thick Pd deposit on MgO(001) at 650 K. GISAXS images recorded in 0.1 s with the incident beam along the MgO [110] (top) and [100] (bottom) directions. White dotted lines show the positions of the four cuts simultaneously used to fit the data, perpendicular and parallel to the surface. (b) Best fit of the cuts (continuous lines) perpendicular (top) and parallel (bottom) to the surface in ((a), bottom), with (circles) and without (dashed lines) size distribution, for a truncated octahedron. In the parallel cut ((b), bottom), the averages of the square of the structure factor appear as blue diamonds. The fitted interference function $S(q)$ (dotted line) is reported on an arbitrary scale; I intensity. (c) Schematic drawing of the fitted, truncated octahedron shape. (d) Simulated GISAXS images obtained after simultaneous fitting of the four experimental cuts. The specular reflectivity (close to $q_y = 0$) was not calculated. (After [11.27] with permission of HighWire Press)

High spatial resolution can be achieved if a constant bias is applied to the rear of the system in order to minimize electrostatic forces originating from residual surface charges. This technique is not able to discriminate between the two elements forming an alloyed particle. SFM can be used on insulating supports. In the example given in Fig. 11.5, SFM is applied to the observation of Au clusters supported on KBr(100) [11.102].

11.3.2 Grazing-Incidence Small-Angle X-ray Scattering (GISAXS)

In GISAXS, a narrow and well-collimated incident x-ray beam hits the system at a grazing angle close to the critical angle for total external reflection. This beam is scattered by the surface due to the nanometric inhomogeneities of the surface (such as steps, kinks, or adsorbed nanoparticles). As a first approximation, the intensity of the scattered light is proportional to the form factor $F(q)$ multiplied by the interference function $S(q)$, where q is the transferred momentum. $F(q)$ and $S(q)$ are the Fourier transforms of the particle shape and the island–island pair correlation function, respectively. From the appearance of the scattered light spectrum and

from its evolution in time, it is possible to extract information on the particle shape as a function of time (for example, during nanoparticle growth or during a chemical reaction). When dealing with an alloyed particle, this technique is not able to provide information about the distribution of the two elements inside the particle. Like SFM, GISAXS can be used on insulating supports. In the example given in Fig. 11.6, GISAXS was successfully applied to the investigation of the growth of Pd particles on MgO(100) [11.27].

11.3.3 X-ray Absorption Spectroscopy (XAS)

XAS is another x-ray technique utilizing synchrotron radiation. This technique allows one to extract in situ structural information on materials which lack long-range order, including amorphous and nanometer-scale clusters [11.103]. One of its drawbacks concerns the difficulty in characterizing stacking faults in metallic particles [11.104].

When the system is irradiated, an adsorption edge is observed if the energy of the x-ray photons is high enough to excite a core electron to an empty energy state or to the continuum. The position of the adsorption edge

depends on the binding energy of the core electrons of each atom, making the technique element specific. The technique which analyzes the first part of the spectrum (about 50 eV above the edge) is called x-ray absorption near-edge spectroscopy (**XANES**), providing useful information about the electronic properties of the atoms involved in the edge adsorption. The features observed in the second part of the spectrum (starting from 50 eV above the edge) give rise to the higher-energy extended x-ray absorption fine structure (**EXAFS**) portion and give information about the local structure around the absorber atoms, that is, the number and type of neighbors. **XAS** is very useful when studying catalytic processes taking place at the surface of nanoparticles. As an example, **XANES** has been used to detect the formation of small metallic copper particles (not detectable via **XRD**) during the reduction of the methanol synthesis catalyst precursor CuO/ZnO and $\text{CuO}/\text{ZnO}/\text{Al}_2\text{O}_3$ [11.105] (Fig. 11.7). Although **EXAFS** can provide information about the neighborhood of the adsorbing atoms, it is not so useful to extract information about the chemical ordering of the alloyed nanoparticles.

11.3.4 Scanning Tunneling Microscopy (STM)

STM is a technique developed in the early 1980s to provide images of solid surfaces with unprecedented resolution. **STM** is based on the tunneling current which flows when a sharp tip gets close to a (semi)conducting surface at a distance of approximately 1 nm or less. The tip is mounted on a piezoelectric material, which allows accurate regulation of the tip movement by applying an external bias. The electronic setup of the **STM** system can control the tip position in two different ways: (i) by maintaining a constant current through the external circuit (constant-current mode), or (ii) by maintaining a constant height of the tip above the sample (constant-height mode). Under ideal conditions, atomistic resolution of the surface can be achieved. **STM** observation of a supported nanoparticle can give useful information on its structure, although direct information on the chemical ordering is difficult to achieve due to the small contrast of different metallic species and tip convolution effects. As an example, in Fig. 11.8, room-temperature **STM** images of 2 Å Pd (Fig. 11.8a), 2 Å Ag (Fig. 11.8b), and 2 Å Pd + 0.4 Å Ag (Fig. 11.8c) deposited on alumina film at 100 K are shown [11.106]. As conductive systems are characterized by a high density of both occupied and empty states around the Fermi level, metallic aggregates (such as those shown in the

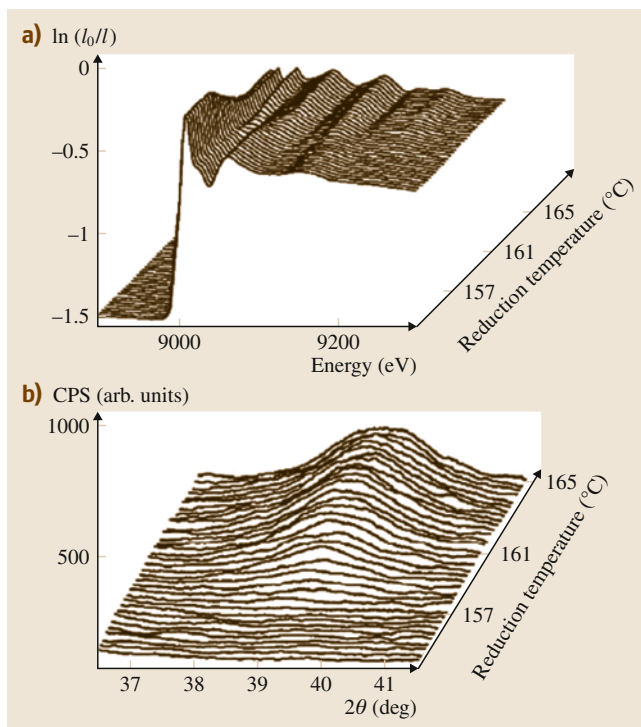

Fig. 11.7 (a) In situ quick EXAFS (QEXAFS) data around the Cu *K*-edge obtained online during the reduction of $\text{CuO}/\text{ZnO}/\text{Al}_2\text{O}_3$ catalyst with Cu : Zn = 30 : 70 (120 s/spectrum) and (b) corresponding **XRD** diffractograms of the Cu(111) reflection, recorded simultaneously (CPS: collected photo signal). (After [11.105] with permission of Springer)

images) usually appear as very bright spots; in this case it results very difficult to achieve atomic resolution and to distinguish between pure and alloyed particles.

STM is one of the few characterization techniques which can in principle provide direct access to structural and electronic information both in vacuum and at atmospheric pressure (and beyond). In fact, despite the necessity of operating with a small gap between the tip apex and the substrate, relatively high gas pressures can be tolerated simply by backfilling a **UHV** chamber [11.107]. Furthermore, a proper choice of low-expansion-coefficient materials reduces the thermal drift in the instrumentation, allowing meaningful observations at elevated temperatures. Despite these two favorable properties of **STM**, the combination of high pressure and high temperature presents a new challenge for the design of the instrumentation. The main limitation of **STM** is that the underlying substrate must be (semi)conductive.

Fig. 11.8a–c Room-temperature STM images of 2 Å Pd (a), 2 Å Ag (b), and 2 Å Pd + 0.4 Å Ag (c) deposited on alumina film at 100 K (image size 100 × 100 nm²). (After [11.106] with permission of Elsevier)

11.3.5 X-ray Photoelectron Spectroscopy (XPS)

XPS is one of the most useful analytical techniques for probing the electronic structure and chemical composition of a sample. In XPS, the system is irradiated with a monochromatic x-ray beam which promotes electronic transitions from the core and valence states of the surface atoms to the continuum.

The emitted photoelectrons are then collected and analyzed using an electron spectrometer. The binding energy (E_b) of the emitted photoelectrons can be calculated from the energy of the incident beam ($E = h\nu$, where ν is the frequency of the x-ray beam) and the measured kinetic energy (E_k) of the electrons via $E_b = h\nu - E_k - \Phi$, where Φ is the work function of the electron analyzer. The work function is the minimum energy necessary to bring an electron from the Fermi energy of the system to the vacuum level. XPS enables quantitative analysis of the surface composition and provides information about the chemical state of elements via measurement of *chemical shifts* in the binding energies of the photoelectrons, i.e., the differences in binding energy with respect to a reference system. The probing depth in XPS depends on the kinetic energy of the emitted photoelectrons, with a minimum of a few angstroms at kinetic energies of around 100 eV.

Because the incident photon energy is lower than 1500 eV in most cases, the kinetic energies of the detected electrons are smaller than this value (after interacting with the surface material). The short mean free path of the emitted electrons in a solid makes XPS a surface-sensitive method. Furthermore, the emitted electrons are also strongly scattered by gas molecules, and XPS is therefore conventionally performed under high-vacuum conditions.

As shown in Fig. 11.9, XPS can be used to quantitatively detect all the elements forming a nanoalloy, discriminating between the different oxidation states of each element; in the example reported here, XPS was

used to estimate the fraction of cobalt atoms reduced from the Co^{2+} oxidation state to Co^0 due to reduction by H_2 [11.108].

XPS can be also used in the investigation of the catalytic properties of pure and alloyed nanoparticles at moderate pressures ($> 10^{-5}$ Torr) in so-called ambient

Fig. 11.9a,b X-ray photoelectron spectra for reduced (a) Pt-Co/ Al_2O_3 and (b) Pt-Co/ NaY measured at Co 2p lines. (After [11.108] with permission of Springer)

pressure photoelectron spectroscopy (APPEs) [11.109], but the attenuation of the electrons due to scattering by gas molecules has to be reduced. The attenuation of the photoelectron signal is proportional to $\exp(-z\sigma p/(k_B T))$, where σ is the electron scattering cross-section, z is the electron's mean free path at pressure p , k_B is the Boltzmann constant, and T is the temperature. The electron attenuation can thus be reduced by placing the sample surface close to a differentially pumped aperture, behind which the pressure drops by several orders of magnitude. This technique can be applied, as an example, to follow the oxidation of the Pd(111) surface (Fig. 11.10) [11.109]. As another example, in the case of a SnPt alloy [11.110], a joint experimental/theoretical analysis of the XPS core-level shifts of the 4d states of the Sn atoms provided useful information for elucidating the surface chemical ordering of the alloy (Fig. 11.11).

11.3.6 Surface X-ray Diffraction (SXRD)

SXRD is another technique which can be used to determine structural parameters at surfaces both under UHV and under high-pressure operating conditions, due to the negligible attenuation of the x-ray beam (due to the low interaction between high-energy x-rays and gases). This, together with the fact that it can be used on insulating substrates, makes the SXRD technique particularly well suited to study the catalytic properties of supported nanoalloys.

In Fig. 11.12, an application of SXRD to the study of the catalytic activity of Pd clusters adsorbed on MgO(100) is shown. When exposed to O₂, the Pd clusters get oxidized (forming a PdO_x phase); when exposed to CO, the oxidation is reversed as CO₂ is formed. These changes can be followed by inspecting the evolution in time of the XRD pattern of the metal nanoaggregates [11.111]. SXRD is not suited to investigate the chemical composition of nanoalloys.

11.3.7 Transmission Electron Microscopy (TEM)

High-resolution TEM (HR-TEM) has made impressive advances in latest years and currently provides a versatile tool for studying the geometric, compositional,

Fig. 11.11 (a) Optimized structure of the SnPt[110] alloyed surface; (b) simulated phonon density of states (PDOS) where the 4d peaks are attributed to the different Sn atoms of the alloy. (After [11.110] with permission of ACS) ►

and electronic structure of a solid with real-space resolution down to the atomic scale [11.112]. Specifically, the ability of TEM to provide information on the local structure and composition of individual nanoclusters makes this technique an essential complement to the

of as images of the atom columns in a sample. In fact, HR-TEM lattice images are obtained by illuminating the sample with a parallel electron beam, and to obtain atomic resolution, the sample must be oriented along a low-index zone axis. The transmitted electrons are collected by a high-angle annular dark-field (HAADF) detector.

To quantify HAADF-STEM intensity profiles, some simple models can be invoked: particles are assumed to possess spherical symmetry, and the HAADF intensities are assumed to depend exclusively on the height of the projected atomic column; the result of such a model is shown in Fig. 11.13; such a procedure allows one

variety of other microscopic and spectroscopic techniques that average information over considerably larger length scales. HR-TEM micrographs are often thought

(a) The image was recorded at pressure of 1.5 mbar of H₂ at 220 °C. The electron beam is parallel to the [011] zone axis of copper. (c) Obtained in a gas mixture of H₂ and H₂O, H₂ : H₂O = 3 : 1, at total pressure of 1.5 mbar at 220 °C. (e) Obtained in a gas mixture of H₂ (95%) and CO (5%) at total pressure of 5 mbar at 220 °C. (After [11.116] with permission of Highwire Press)

to estimate the number of atoms in each column and accurately estimate the cluster size [11.113, 115].

Aberration-corrected HR-TEM has been developed to improve the resolution of TEM. The images can be aberration-corrected by hardware or by software, and it is reported that a combination of both procedures provides optimal results (Fig. 11.14, [11.114]). Essentially all the commercial or free available software packages for calculating HR-TEM images are capable of computing images from nanowires, nanotubes, and nanoparticles.

As the scattering section depends on the atomic numbers of the atoms (the contrast being roughly proportional to Z^3 , where Z is the atomic number), this technique can be used to discriminate between the different elements forming an alloyed nanoparticle, if they differ significantly in atomic number. An example dis-

cussed in more detail in Sect. 11.4.1 is the observation of Ag-Au alloyed nanoclusters, where a sufficiently high contrast led to the identification of a Janus-like chemical order over a long time scale [11.118].

In the field of heterogeneous catalysis, a novel atomic-resolution environmental TEM (E-TEM) has been recently developed [11.100] to investigate gas/solid reaction processes under controlled and realistic conditions of pressure and temperature. To this aim, the whole electron microscope was modified by the introduction of a fully integrated and permanently mounted environmental cell (ECELL) system based on a multistage differential pumping system. An application is reported in Fig. 11.15, which shows the evolution of the shape of Cu nanoparticles (supported on ZnO), under the action of a mixture of H₂ and CO at different values of temperature and total pressure [11.116].

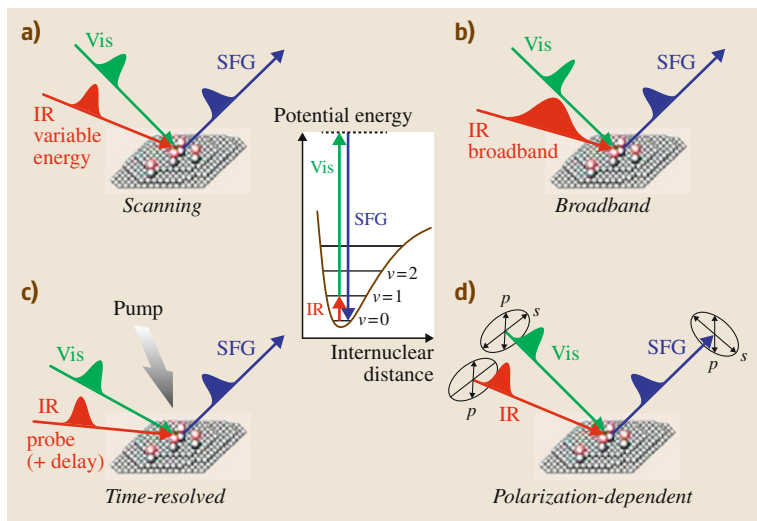

Fig. 11.16a–d Modes of operation and potential energy plot of vibrational IR-Vis sum-frequency generation (VSFG). In the case of a vibrational resonance of an adsorbed molecule (center plot, where v indicates vibrational levels), visible light is generated at a frequency that is the sum of the frequencies of the two incident optical fields ($\omega_{\text{SFG}} = \omega_{\text{IR}} + \omega_{\text{vis}}$). The different modes of operation include (a) scanning, (b) broadband, (c) pump-probe (time-resolved), and (d) polarization-dependent VSFG. (After [11.117] with permission of MRS)

11.3.8 Vibrational Sum-Frequency Generation (VSFG)

A technique which is particularly useful in the characterization of catalytic reactions taking place at the surface of metallic nanoparticles is laser spectroscopy based on the second-order nonlinear optical process of sum-frequency generation [11.98, 99] (Fig. 11.16). The system is irradiated by two (laser) light waves of different frequencies; they interact in a medium characterized by a nonlinear susceptibility tensor $\chi^{(2)}$ and generate a wave at the sum of their frequencies. To acquire an SFG vibrational spectrum during a chemical reaction, two picosecond laser pulses are spatially and temporally overlapped on the sample. One input beam is in the visible range at a fixed frequency (ω_{vis}), while the second is tunable in the mid-infrared (IR) region (ω_{IR}) to probe the vibrational modes of the surface species. When the high-energy virtual state relaxes, light is generated at a frequency that is the sum of the frequencies of the two incident optical fields ($\omega_{\text{SFG}} = \omega_{\text{IR}} + \omega_{\text{vis}}$),

resulting in a signal in the visible region. By tuning the wavelength of the IR beam and monitoring the intensity of the SFG output, an adsorbate vibrational spectrum is obtained as a plot of the SFG intensity against the IR wavenumber. An example is shown in Fig. 11.17, where this technique has been applied to methanol oxidation on Pd- Al_2O_3 [11.119].

Other spectroscopic techniques can be used to characterize the surface of nanoparticles: For example, one can monitor the infrared (IR) spectrum of adsorbed CO species [11.120], extracting information on the status of the surface. More recently, advances in electron paramagnetic resonance (EPR) have been realized to allow identification of extremely low concentrations of unpaired spins, also located at the solid-vacuum interface [11.121]. Finally, before the advent of advanced microscopy and spectroscopic techniques, chemisorption data or in general reactivity data were widely used to characterize, at least semiquantitatively, the structure (e.g., the dispersion and surface composition) of alloy heterogeneous nanocatalysts [11.2, 22, 83, 84].

11.4 Properties

As recalled in the Introductory, the expansion of possibilities afforded by combining two different metal species is truly vast. Practically any interesting property of metal nanosystems can in principle be tuned and the associated difficulties solved by judicious mix-

ing of different species. This section first describes some of the knowledge on the novel phenomena that are encountered at the structural level in this field (Sect. 11.4.1), pointing out the great freedom and also the unexpected findings that have emerged in recent

Fig. 11.18a–c Face-centered cubic (fcc) clusters: (a) octahedron, (b) truncated octahedron, and (c) cuboctahedron. Each cluster is shown in four views. An octahedron is made up of two square pyramids sharing a common basis. Its surface consists of eight triangular close-packed (111) facets, but the structure has a high surface-to-volume ratio. Polyhedra with a lower surface-to-volume ratio are obtained by symmetrically truncating the six vertices of an octahedron, thus obtaining square and hexagonal (or triangular, see later) facets. A truncated octahedron can be characterized by two indexes: n_1 is the length of the edges of the complete octahedron; n_{cut} is the number of layers cut at each vertex. In the figure, for the octahedron in (a) $(n_1, n_{\text{cut}}) = (7, 0)$, for the truncated octahedron in (b) $(n_1, n_{\text{cut}}) = (7, 2)$, and for the cuboctahedron in (c) $(n_1, n_{\text{cut}}) = (7, 3)$. A perfect truncated octahedron thus has a number of atoms, $N_{\text{TO}}(n_1, n_{\text{cut}}) = 1/3(2n_1^3 + n_1) - 2n_{\text{cut}}^3 - 3n_{\text{cut}}^2 - n_{\text{cut}}$. This equation defines the series of magic numbers for truncated octahedron structures. The square facets have (100) symmetry and edges of $n_{\text{cut}} + 1$ atoms. The (111) facets are not in general regular hexagons. In fact, three edges of the hexagons are in common with square facets, thus having $n_{\text{cut}} + 1$ atoms, while the remaining three edges have $n_1 - 2n_{\text{cut}}$ atoms. Regular hexagons are thus possible if $n_1 = 3n_{\text{cut}} + 1$; truncated octahedra with regular hexagonal facets are referred to as regular truncated octahedra. When $n_1 = 2n_{\text{cut}} + 1$, the hexagonal facets degenerate to triangles and the cuboctahedron is obtained, which is usually not energetically favored because of its large (100) facets. (After [11.122] with permission of APS)

years, with the discovery of novel structural motifs peculiar to multicomponent systems. The rest of the section is devoted to the fascinating properties of alloy nanoparticles, from the chemical ones that are exploited in the field of heterogeneous catalysis to the optical ones studied by Michael Faraday and the more

recent interest on magnetism. The mechanical properties that are obtained by nanostructuring bulk alloys are treated in Sect. 11.5. Clearly, this represents only a subset of the recent developments, achievements, and realizations. Our aim is to give a flavor of what has been and is currently being pursued in this field and some basic understanding that should enable the reader to follow the relevant literature. Most subsections include a brief part on the theoretical methods as available or appropriate. Theoretical simulations have already made a very important contribution to the understanding and a priori prediction of the structural properties of nanostructured alloys (Sect. 11.4.1). Moreover, also in the field of the catalytic, optical, magnetic, and mechanical properties, computational methods are nowadays becoming able to treat realistic systems with sufficient accuracy and will make a decisive contribution to future advances in both basic and oriented research.

11.4.1 Structural Properties of Alloyed Nanoparticles

In this section, the morphologies and chemical order patterns of metallic nanoalloys are briefly described. Due to the *greedy* and *fluxional* character of the metal–metal interaction [11.19, 20], i.e., the fact that metal atoms can sustain a wide range of coordination numbers (up to 12–14) and that the energy barriers between various structures are not too high so that particles may transition among them in working conditions, metal nanoparticles and nanoalloys exhibit an impressive variety of different morphologies [11.91, 123] and mixing patterns [11.25]. The study of the structure of metal particles is thus at the forefront of current research, due to both unsolved fundamental challenges and its close links with particle functions and properties, and its relevance in technological applications [11.26]. We will discuss in particular particles either free or supported on a substrate, leaving aside for reasons of space the vast field of particles or clusters coated by a protective layer of surfactants [11.6, 54, 58].

Morphology in the Gas Phase

We start by describing the morphology, or structural motifs, of free nanoparticles [11.123], distinguished into crystalline, noncrystalline, and those peculiar to very small clusters.

Crystalline Structures. In this family the atoms of the clusters are positioned at the crystalline sites character-

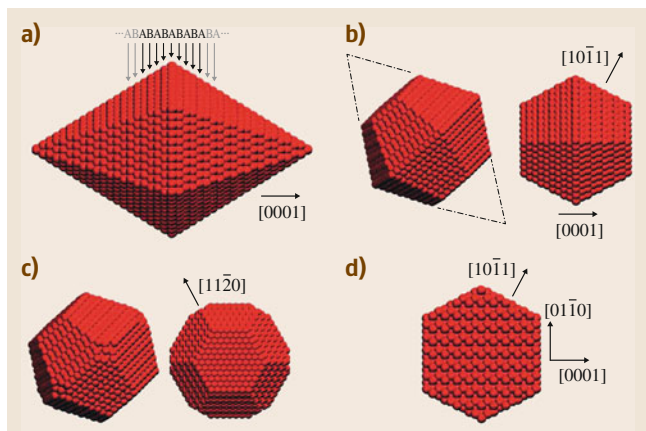

Fig. 11.19a–d Morphology of the *hcp* motif. The *hcp* motif is obtained by truncating hexagonal bipyramids (a), whose axis is parallel to the *c*-axis of the *hcp* lattice of the metal. The first cut (b) eliminates top and bottom vertices of the pyramids, thus generating hexagonal (0001) faces. The second cut (c) eliminates lateral vertices, creating small ($11\bar{2}0$) facets, with their typical zigzag atomic arrangement. The final cut (d) is due to the contact with the substrate and generates a large ($11\bar{2}0$) face. Close-packed planes are perpendicular to the substrate. (After [11.125] with permission of ACS)

izing the metal in its bulk form. When cutting a particle from a bulk crystal, the driving force is to minimize the surface energy of the resulting cluster. One way is to make cuts by exposing only close-packed (111) facets: the resulting shape is the octahedron (Fig. 11.18a), that is, two opposite square pyramids sharing a basis. Even though all the octahedron faces are close packed, the particle shape does not optimize the surface energy because of its high surface-to-volume ratio. Clusters with more spherical shapes can be obtained by cutting the vertices of the octahedron, thus producing a truncated octahedron (TO) (Fig. 11.18b). The TO surface has eight hexagonal close-packed (111) facets and six square (100) facets. A more (or less) deep cut determines an increase (or decrease) of the square facets at the expense of the close-packed ones; when the shape of the (111) facets becomes a triangle, the resulting cluster structure is called a cuboctahedron (CO, Fig. 11.18c). In general, the CO is not favored with respect to other TO because of the too large (100) facets. For sufficiently large sizes, the optimal particle shape is given by the canonical Wulff construction [11.124], a model developed to determine the lowest-energy shape of macroscopic crystals via minimization of the surface energy. According to this construction, the best trun-

cated octahedron structure should fulfil the condition

$$\frac{\gamma(100)}{g\gamma(111)} = \frac{d(100)}{d(111)},$$

where $\gamma(100)$ and $\gamma(111)$ are the surface energies of the (100) and (111) facets, respectively, while $d(100)$ and $d(111)$ are the distances of the facets from the center of the cluster. The higher the surface energy of a given facet, the greater its distance from the center of the cluster. The same relation also applies to any other surface plane.

Several metals possess a face-centered cubic (fcc) structure in the bulk form. Some metals (such as cobalt and titanium) are hexagonal close packed (hcp) in the bulk form; when cutting an *hcp* crystal, the solid which is obtained is shown in Fig. 11.19: the *hcp* nanodots are truncated hexagonal bipyramids whose axis coincides with the *c*-axis of the *hcp* lattice [11.125]. As in the case of the TO, also in this case it is possible to reduce the surface-to-volume ratio by cutting the vertices of the solid, as shown in Fig. 11.19. Analogous reasoning holds for body-centered cubic (bcc) clusters.

Noncrystalline Structures. Noncrystalline motifs, i. e., structures which cannot give rise to a periodic pattern because they contain, e.g., fivefold symmetry axes, are an alternative way to obtain low-energy structures [11.123].

The Mackay icosahedron (Fig. 11.20) was the first noncrystalline motif discussed, in 1962, and corresponds to one of the Platonic solids. This is a structure with fivefold rotational axes. Icosahedral clusters are limited by (111) close-packed facets only, thus minimizing the cluster surface energy. However, this is obtained at the expense of a volume contribution due to the fact that the atoms are not in their crystalline positions; radial intershell bonds are compressed, whereas intrashell bonds are expanded. Therefore Mackay icosahedra are highly strained structures, suggesting that icosahedra could be expected to be the most favorable structures only at small sizes.

Icosahedra are not the only possible noncrystalline structures. Another motif is represented by the Ino decahedron (Fig. 11.21a). This structure is formed by two pentagonal pyramids sharing a base; its surface has only (111) close-packed facets, but its shape is very far from being spherical.

Truncation of the five edges limiting the common basis of the pyramids to expose (100)-like facets is advantageous (Fig. 11.21b), but this cut does not usually produce the best possible decahedron. In 1984,

Fig. 11.20 Icosahedral clusters. The Mackay icosahedron is a noncrystalline structure organized in shells. An icosahedron with k shells has $N_{\text{Ih}}(k) = 10/3k^3 - 5k^2 + 1/3k - 1$ atoms (so that the series of magic numbers is 1, 13, 55, 147, ...). The icosahedron in the figure has $k = 4$ shells. An icosahedron with k shells has the same number of particles as a cuboctahedron with $n_{\text{cut}} = k - 1$. An icosahedron has 20 triangular facets of side k and 12 vertices. Each pair of opposite vertices lie along a fivefold symmetry axis. An icosahedron can be thought of as composed of 20 fcc tetrahedra sharing a common vertex in the central site. When 20 regular tetrahedra are packed around a common vertex, large interstices remain. To fill these spaces the tetrahedral must be distorted, thus generating a huge strain on the structure. Intershell distances are compressed, while intrashell distances are expanded. The facets of an icosahedron are of distorted (111) symmetry. Adatoms deposited on the facets of a Mackay icosahedron can be placed on sites of either fcc or hcp stacking. Islands of fcc stacking are part of the next Mackay shell, while islands of hcp stacking form a so-called anti-Mackay overlayer. (After [11.122] with permission of APS)

Marks proposed a different cut, with reentrances exposing further close-packed facets separating neighboring (100)-like facets (Fig. 11.21c). Marks decahedra achieve better optimization of the surface energy than truncated octahedron structures. Decahedra are also strained structures, although the strain is much smaller than for icosahedra. This means that the icosahedral motif should be the most favored motif at small sizes, and truncated octahedron clusters are expected for large sizes; truncated decahedra could be favored in an intermediate range [11.126].

The explosive surge of activity in recent years (see, e.g., the collection of data in the Cambridge crystallographic data base (CCDB [11.127]), has enriched the set of classical structural motifs (i. e., decahedral, icosahedral, and crystalline) with new additions.

Among these, a notable class is that of polyicosahedra (pIh) [11.128, 129]. pIh structures (Fig. 11.22) are built by packing elementary icosahedra (Ih) of 13 atoms in such a way that core (interior) atoms in the structure are surrounded by a complete Ih₁₃ shell [11.128]. They have been predicted to be kinetically favored due to coalescence or rapid growth,

Fig. 11.21a–c Decahedral clusters: (a) regular decahedra, (b) Ino truncated decahedra, and (c) Marks truncated decahedra. A decahedron is made up of two pentagonal pyramids sharing a common basis. It has a single fivefold axis and is formed by five tetrahedra sharing a common edge along the fivefold axis. When five regular tetrahedra are packed, gaps remain, but they are smaller than in the case of the icosahedron. These gaps are filled by distorting the tetrahedra, thus introducing some strain. Regular decahedra (first row) are limited by ten close-packed (111)-like facets, but have a large surface-to-volume ratio, which can be lowered by truncating the edges around the common basis, thus obtaining the Ino decahedron with five (100)-like facets. An even better structure is the Marks decahedron, obtained by introducing reentrances that separate the (100)-like facets (third row). A decahedron is characterized by three integer indices (m, n, p), where m and n are the lengths of the sides of the (100) facets, perpendicular and parallel to the axis, respectively, and p is the depth of the Marks reentrance. A regular decahedron has indices of the form ($m, 1, 1$) [the (5, 1, 1) decahedron is shown in the top row], Ino decahedra have indices ($m, n, 1$) with $n > 1$ [the (4, 2, 1) Ino decahedron is shown in the second row], and Marks decahedra have (m, n, p) with $n, p > 1$ [the (2, 2, 2) Marks decahedron is shown in the third row]. A Marks decahedron has $h = m + n + 2p - 3$ atoms along its symmetry axis and a total number of atoms given by $N_{\text{M-Dh}} = (30p^3 - 135p^2 + 207p - 102)/6 + \{5m^3 + (30p - 45)m^2 + [60(p^2 - 3p) + 136]m\}/6 + \{n[15m^2 + (60p - 75)m + 3(10p^2 - 30p) + 66]\}/6 - 1$. From this formula it follows that a Ino decahedron has $N_{\text{Ino}} = [5m^3 - 15m^2 + 16m + n(15m^2 - 15m + 6)]/6 - 1$ atoms. For $n = m$ and $p = 1$ [square (100)-like facets] a decahedron thus has the same number of atoms as an icosahedron of m shells and as a cuboctahedron with $n_{\text{cut}} = m - 1$. Finally, a regular decahedron has $N_{\text{Dh}} = (5m^3 + m)/6$ atoms. (After [11.122] with permission of APS)

but also to be thermodynamically stable for given isolated particles [11.130], especially for binary metal nanoclusters (or nanoalloys) in proper combinations of the constituent metals [11.131, 132]. In fact, by mixing two metals of different atomic size and by adopting a core-shell chemical ordering, one can achieve great stabilization of an *Ih*-type structure if the smaller element segregates into the core and if the size mismatch is of the proper amount. *plh* motifs are important also because they can be seen as the finite-size analogs of *Frank-Kasper* bulk phases [11.133] and thus, ultimately, quasicrystals [11.134, 135].

Fig. 11.23 (a) Leary tetrahedron fragment for the composition $\text{Pd}_{28}\text{Pt}_{28}$. (b) Leary tetrahedron structure with different shells indicated by different colors. (c) Leary tetrahedron structure for $\text{Pd}_{49}\text{Pt}_{49}$. Pd and Pt atoms are represented by dark- and light-blue spheres, respectively, in (b) and (c). (After [11.37] with permission of RSC)

Fig. 11.22 Magic core-shell *plh* clusters; *plh* clusters are built by packing elementary Ih_{13} clusters, as shown in the top row, where three different fragments of the *plh*⁷ structure are given. From left to right, the fragments comprise one, two, and four interpenetrating Ih_{13} . Below, a selection of magic core-shell *plh* is given. Each *plh* is shown in four views; in two of them the Ag atoms (grey color) are represented by small points to show the arrangement of the core (Ni or Cu, orange color) atoms. The (27;7)*plh*⁷ has a decahedral Ni or Cu core of 7 atoms, and the 27 Ag atoms are placed in an anti-Mackay overlayer. The (32;6)*plh*⁶ is a pancake structure, with the six inner atoms placed on a regular hexagonal ring. The (30;8)*plh*⁸ is the perfect core-shell structure including the maximum number of core atoms at size 38. The (32;13)*plh*¹² is the complete anti-Mackay icosahedron of size 45, including a perfect Ih_{13} core. It is made of 12 interpenetrating Ih_{13} sharing the central atom as a common vertex. (After [11.128] with permission of APS) ◀

Another important novel family is represented by hybrid motifs, such as hybrid decahedral/close-packed structures, in which a close-packed core in the form of a trigonal pyramid or bipyramid is surrounded by atoms growing on the core faces in *hcp*(111) stacking plus further atoms arranged along edges between two faces, thus creating a local decahedral arrangement ([11.37, 136, 137], Fig. 11.23).

The reason why the occurrence of these hybrid structural motifs can be favored in nanoalloyed particles can be rationalized. Suppose that one mixes two species with very different cohesion in the bulk, and suppose also that the size mismatch between the two species is small or such that the more cohesive element also presents the smaller size. In these conditions, it is not unreasonable to expect a core-shell arrangement with a core segregation of the latter species. Moreover, once this species achieves full coordination in the core (i. e., coordination number = 12), it will tend to arrange in a close-packed (*cp*) configuration. The less cohesive species, instead, being surface-segregated and thus low-coordinated, will tend to adopt a noncrystalline, fivefold arrangement.

These are hybrid structures which combine a close-packed core with a decahedral or icosahedral surface. One such example is the *Dh-cp* (*DT*) structure described in [11.138] for $(\text{Pd-Pt})_{34}$ (Fig. 11.24a). At $\text{Pd}_{14}\text{Pt}_{20}$ composition, the internal core made of Pt atoms is a double tetrahedron or trigonal bipyramid (i. e., two tetrahedra sharing a face), while the Pd shell grows in *hcp* stacking on the faces and at edges. The *DT* structure can be thought of belonging to the family of so-called

Leary tetrahedra [11.37, 136]. Note, however, that at these small sizes the interplay of bond count and bond strength is subtle, and it turns out that the Leary tetrahedron is not favored at its own magic number ($N = 44$) but in the size range immediately below it (around 34 atoms).

Another example of a hybrid structural motif is the **Oh-lh** structure described in [11.137] for (Ag-Pt)₃₈ (Fig. 11.24b). This structure is similar to the TO₃₈ structure as it has an internal octahedral core. However, the surface atoms do not grow exactly on top of the (111) faces of the internal octahedron (as would happen in a TO₃₈ arrangement) but are placed according to a distorted arrangement, in such a way that only two square faces (instead of six as in TO₃₈) and no hexagonal faces are created. From an internal perspective, it resembles two double icosahedra joined by the central atoms, and in this sense it can be considered as an example of a mixed fivefold-symmetric/closed-packed arrangement.

To summarize, mixing two different metal species can give rise to novel structural motifs, such as **plh** or hybrid ones, that are either unknown or not favorable for pure species. Core-shell or multishell configurations in general are ubiquitous. Among these, those realized, e.g., in fivefold **plh** structures, represent an efficient way to express at the nanoscale the segregation or immiscibility tendency present in the bulk with additional energetic benefits. The idea that metals immiscible in the bulk could mix at the nanoscale, i.e., by forming core-shell segregated configurations, had been hypothesized for some time [11.22, 140], being spectacularly confirmed by the advent of improved microscopy, spectroscopic, and theoretical characterization techniques.

Very Small Clusters. To complete this general overview, the case of very small clusters (composed by, say, fewer than 20 atoms) deserves some consideration. When the size is very small, almost all the atoms are undercoordinated, resulting in stabilization of *exotic* structures. In the case of gold clusters, for example, the relativistic contraction of the Au 6s orbital concomitant with a significant shortening of the interatomic bond distances (typically by 0.25 Å) results in increased overlap between the 5d orbitals of neighboring atoms. The increased tendency towards strong directional chemical bonds explains the stabilization of planar structures [11.139] for very small nuclearities (fewer than 12 atoms) (Fig. 11.25); the transition to compact structures takes place above size 12–13, due to the lengthening of the bond distances at increased

Fig. 11.24a,b Two hybrid fivefold-symmetry/close-packed structures. **(a)** Dh-cp (DT) at size $N = 34$, and **(b)** Ohlh at size $N = 38$

coordination numbers. Moreover, in the size range between 16 and 18 atoms, hollow cages have been experimentally detected and theoretically studied. These hollow golden cages (*bucky gold*), which are shown in Fig. 11.26, have average diameter > 5.5 Å and can easily accommodate one guest atom inside [11.141, 142].

Morphology of Supported Particles

We now describe the morphology of nanoparticles supported on a regular substrate.

The Wulff–Kaischew Model. Metal nanoparticles can be stabilized or directly grown on a support, and a common choice of substrate is represented by oxide surfaces.

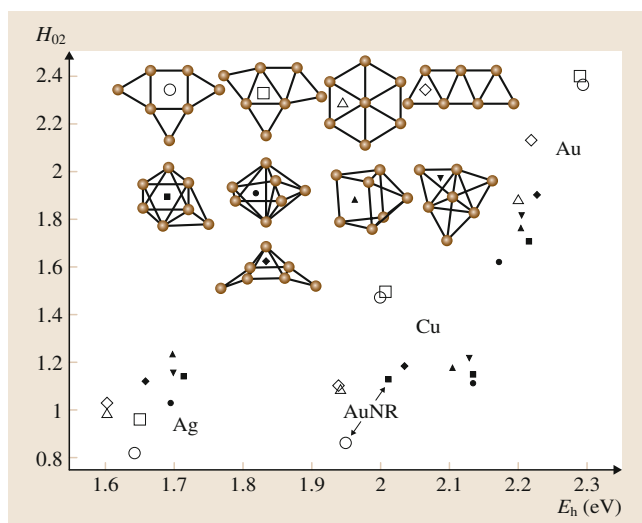

Fig. 11.25 Correlation between the sd hybridization index H_{02} and the binding energy per atom; a larger value of H_{02} indicates stronger sd hybridization. (After [11.139] with permission of APS)

(b) The hollow gold cages with diameters $> 5.5 \text{ \AA}$. (c) The pyramid-like clusters, which resemble bulk gold. (After [11.141] with permission of NAS)

The equilibrium shape of a supported nanoparticle can be different from that in the gas phase, and the problem of the equilibrium shape of supported nanoparticles was first solved by Kaischew via the Wulff–Kaischew construction, an extension of the Wulff criterion ruling the equilibrium shape of large clusters in the gas phase [11.91]. As can be observed in Fig. 11.27, due to the adhesion between the metal particle and the substrate, a larger portion of the cluster can be cut off, resulting in an asymmetric shape with respect to the central plane of the particle. In practice, the adhesion energy of the particle to the substrate plays the role of a surface energy in the Wulff construction. To elucidate how this criterion can be used to rationalize the structure of supported metal clusters, let us examine the results of global optimization searches carried out on four pure metals (Ag, Au, Pd, and Pt) adsorbed on $\text{MgO}(100)$ [11.143, 144]. In general, the shape of the clusters is the result of the competition between metallic bond and metal–substrate interaction. Typically, within each structural motif, the clusters tend to grow accord-

ing to a given shape which optimizes, for example, the metal–substrate interaction energy, until this requires too high an energetic price, at which point the competing quantity (the metal–metal interaction energy) sets in, overcoming the corresponding energy penalty and the structure *collapses*, or better realizes a transition into a different shape.

Simulations on Ag, Au, Pd, and Pt particles adsorbed on $\text{MgO}(100)$ singled out three dominant motifs:

1. fcc clusters in (001) epitaxy (Fig. 11.28a,b)
2. fcc clusters in (111) epitaxy (Fig. 11.28c,d)
3. Decahedral clusters which adhere to the substrate with a pseudo-(001) facet.

Icosahedral clusters do not achieve good matching with the substrate, and are therefore not favorable for these metal/support combinations. Concerning fcc clusters, the competition between the (001) and the (111) epitaxy is due to the following reason: The (001) epitaxy has stronger adhesion energy per unit contact area, due to its better matching with the oxygen atoms of the square-symmetry substrate, especially when the lattice mismatch between metal and oxide is small. However, for (111) epitaxy, this can be compensated by a larger contact area, so that the total adhesion energy may become even larger than for (001) epitaxy.

In Ag/ $\text{MgO}(001)$, extensive calculations [11.143] predict that the fcc(001) motif is dominant in the size range up to 3000 atoms at least, followed by the decahedral and by the fcc(111) motifs. This compares well with the experimental data on this system [11.145, 146], which find the fcc(001) epitaxy dominant for all sizes. On the contrary, calculations on the Au/ $\text{MgO}(001)$ system [11.143] reveal close competition between the fcc epitaxies, with decahedral clusters being higher

Fig. 11.27 Schematic representation of the equilibrium shape of a supported crystal. The Wulff shape of the free crystal is truncated at the interface by Δh_s , which is proportional to the adhesion energy. (After [11.91] with permission of Elsevier)

Fig. 11.28 (a,b) Side and bottom views of a $\text{fcc}(001)$ cluster. (c,d) Side and bottom views of a $\text{fcc}(111)$ cluster. In all panels, oxygen atoms are in dark gray (red) and magnesium atoms are in white (light gray). In the bottom views (b,d), substrate atoms are represented by small spheres so that the contact epitaxy of the cluster is visible. (After [11.143] with permission of AIP)

in energy. For sizes below around 1000 atoms, the $\text{fcc}(001)$ epitaxy prevails. Then, a crossover range follows, in which both fcc epitaxies are very close in energy, and finally, for sizes above 1500 atoms, the $\text{fcc}(111)$ epitaxy prevails. These results are again in agreement with the available experimental data. In fact, for sizes below 1000 atoms, only $\text{fcc}(001)$ structures are observed [11.29] (Fig. 11.29), while for larger nanoparticles both epitaxies are produced [11.91].

The Pd and Pt cases are more controversial. The calculations [11.144] predict a crossover between (001) and (111) epitaxies at rather small sizes, well below 1000 atoms. This size-dependent crossover has not been observed experimentally. However, the experiments observe a temperature-dependent change of epitaxy in Pt/MgO(001) [11.148], which is still to be investigated theoretically. In Fig. 11.30, an STM image of Pd clusters growing in (111) epitaxy on amorphous alumina is shown [11.147]. It should be noted that for all these metals the Wulff–Kaischew construction predicts that the (111) epitaxy should prevail in the large size limit [11.144]. In the small size regime, to reconcile the results of the Wulff–Kaischew model with the experimental evidence, it is possible to define a size-dependent adhesion energy per unit contact area (in the

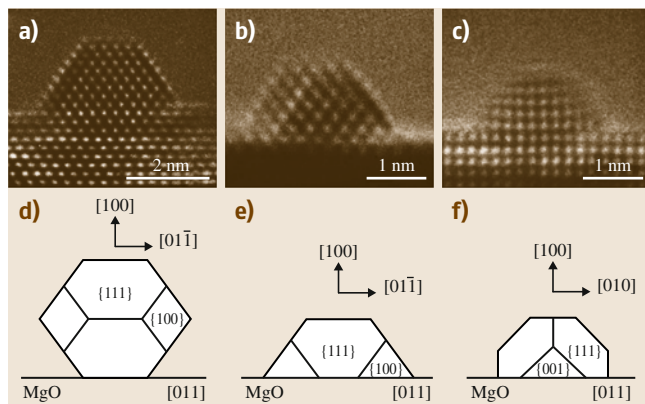

Fig. 11.29a–f Au clusters deposited on MgO. (a) HR-TEM image of a truncated octahedral cluster in a $\langle 011 \rangle$ zone axis orientation. (b) Half-octahedral cluster in a $\langle 011 \rangle$ orientation. (c) Half-octahedral cluster in a $\langle 001 \rangle$ orientation. (d–f) Profiles of the clusters shown in (a–c), respectively, with indexation of the crystallographic directions and the faces. (After [11.29] with permission of APS)

Fig. 11.30a,b Atomic-resolution images of crystalline nanosize Pd clusters. (a) 95 × 95 Å², $I_t = -0.8$ nA, $V_s = -5.0$ mV. (b) 45 × 45 Å². The resolution is kept a few layers down the sides, allowing identification of the side facets. The dots indicate atomic positions consistent with a (111) facet. $I_t = -1.8$ nA, $V_s = -1.5$ mV. (After [11.147] with permission of APS)

framework of a size-dependent Wulff–Kaischew construction), so that the crossover to the (001) epitaxy with decreasing size can be recovered [11.144]. In fact, the adhesion energy per unit contact area of the $\text{fcc}(001)$ epitaxy increases appreciably as the nanoparticle adheres with a smaller facet, because the contact atoms can more easily accommodate the lattice mismatch with the substrate. This is especially evident for Pd and Pt. On the contrary, the adhesion energy per unit contact area of the $\text{fcc}(111)$ epitaxy is almost constant with size.

Interface-Stabilized Morphologies. In the case of an appreciable interaction between the support and the metal particles, exotic structures are possible which are stabilized by the substrate and that, in some cases, have no counterpart in the gas phase. A well-understood example is given by Ni particles on MgO(100) [11.125]; in this system, due to the large size mismatch between the nearest-neighbor distance in bulk Ni and the O–O distance in the MgO substrate, the preferred structural motif is made of *hcp* nanocrystals, whose close-packed planes, alternating in . . . ABAB . . . stacking, are *perpendicular* to the oxide substrate and oriented along the [100] direction of the substrate (Fig. 11.31). Theoretical simulations show that, as the size of the clusters increases above $N = 40$, the lowest-energy structures are *hcp* for almost all sizes.

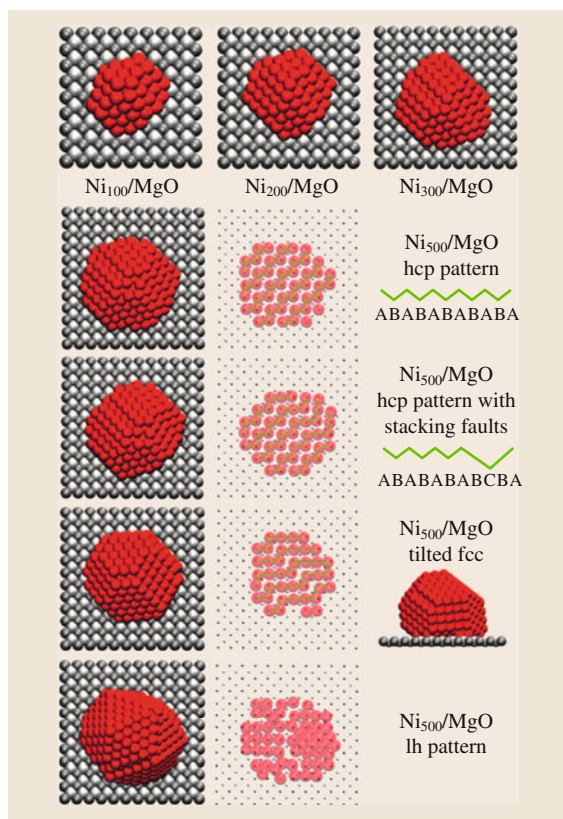

Fig. 11.31 Global minima of Ni/MgO nanodots (of *hcp* structure) shown for $N = 100, 200$, and 300 atoms. For $N = 500$ we show, *from top to bottom*, an unfaulted *hcp* structure, a *hcp* structure with a stacking fault (global minimum), a *fcc* structure, and an icosahedral (*Ih*) structure. (After [11.125] with permission of ACS)

The morphology of the *hcp* nanodots is easily understood: the *hcp* nanodots are the same truncated hexagonal bipyramids shown in Fig. 11.31, whose axis coincides with the c -axis of the *hcp* lattice. These bipyramids are cut to expose (0001), (1011), and small (1120) surfaces. A larger (1120) face is in contact with the substrate, where Ni atoms assume a typical configuration in zigzag rows. The driving forces leading to the stabilization of the *hcp* nanodots can be extended to other metal/oxide couples: Pd/CaO, Pt/CaO, Ni/CoO, and Co/MgO. It is to be noted that Ni, Pd, and Pt are *fcc* rather than *hcp* in the bulk, so that a transition to *fcc* configurations is expected to occur with increasing size of the particles. In fact, experiments on Ni particles on MgO(100) [11.149] observe the *hcp* morphology at small sizes and locate a transition to the usual *fcc*(001) structures for diameters larger than about 5 nm. At the theoretical level, the comparison of *hcp* and *fcc*(001) motifs as a function of size locates this transition between 2000 and 2500 atoms, corresponding to cluster diameters of about 4.5 nm, in excellent agreement with experimental data.

Another case of structures stabilized by the support is offered by Au/MgO: in the same size range between 25 and 40 atoms in which Pd clusters develop *fcc* epitaxial configurations [11.150], first-principles simulations predict that hollow gold cages are the most favorable structures on the MgO(001) surface. In particular, the interaction with the substrate stabilizes a novel class of hollow cage nanoparticles, namely open pyramidal hollow cages, which have no counterpart in free-space clusters [11.151].

Other *exotic* epitaxial relationships can be conceived, and have been actually found in more complex cases, such as in particular binary metal clusters. The case of CoPt particles adsorbed on MgO(100) [11.152] is briefly reviewed here, as this system is important in magnetism [11.153] and catalysis [11.154]. Pt clusters with $N \leq 100$ exhibit amorphous-like (or, better, reconstructed icosahedral) configurations [11.155], and become *fcc*-like when adsorbed on the MgO(100) surface [11.144]. Co clusters in the same size range are decahedral, and become *hcp* when adsorbed on the same surface [11.125]. Bulk solid CoPt at 50–50% composition presents an ordered phase of $L1_0$ structure, with tetragonal crystal lattice of alternating homogeneous Pt and Co planes along a (001) axis. However, for free nanoparticles smaller than about 3 nm, *plh* structures are predicted [11.156, 157] and experimentally observed [11.153, 158]. The reason for this transition to noncrystalline structure at small sizes is that a certain

type of sixfold-symmetric plh configuration maximizes the number of mixed bonds [11.152]. When adsorbed on the $\text{MgO}(100)$ surface, it is found that plh clusters can be satisfactorily accommodated on the substrate

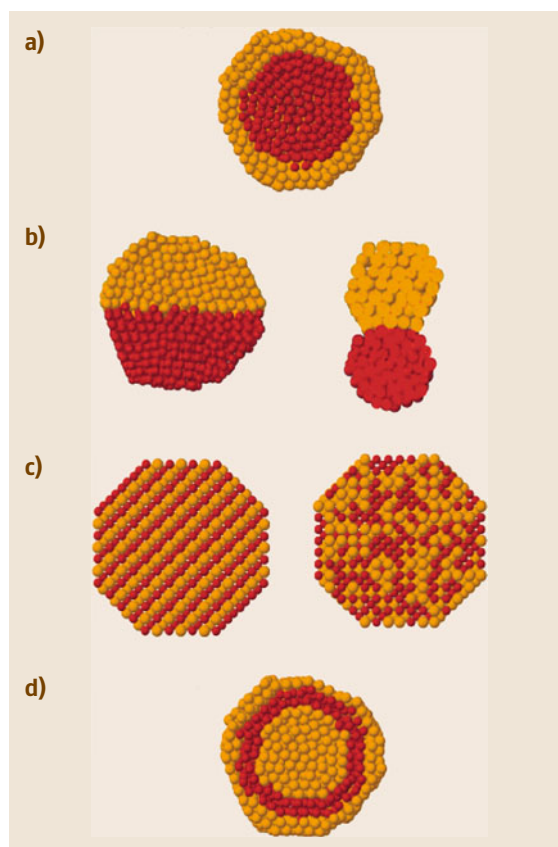

Fig. 11.33a–d Schematic representation of some possible mixing patterns: core-shell (a), subcluster segregated (b), mixed (c), three shell (d). The pictures show cross-sections of the clusters. (After [11.25] with permission of ACS)

while preserving their gas-phase shape by simply segregating cobalt at the interface. Some examples of supported CoPt clusters are shown in Fig. 11.32. From these examples, it can be seen that plh structures can accommodate on the surface either by adding lateral Co atoms at the interface or by tilting their sixfold-symmetry axis and by inserting further Co atoms to fill up the void so created (Fig. 11.32). Moreover, a tilted plh6 can match with another one tilted in the opposite way, creating a structure which achieves shell closure at $N = 64$.

Chemical Ordering

Once the morphology of an alloyed nanoparticle has been determined, its complete characterization requires the determination of the chemical ordering pattern. There exist four main types of mixing patterns [11.25].

Fig. 11.34a–f Bright field (BF) HR-TEM images (a) and (b) showing typical structure of Ag-Au clusters from a fresh sample ($\theta = 3\%$ and $d_6 \pm 0.5$ nm). (a) Icosahedron, (b) decahedron, (c) BF, and (d) HAADF-STEM images taken simultaneously showing a typical core-shell cluster from an aged sample. (e) BF TEM and (f) HAADF STEM images of two typical Janus particles in an aged sample. Fast Fourier transforms (FFT) of selected areas on (e) and (f) are shown in the insets. (After [11.118] with permission of AIP)

Subcluster Segregated Nanoalloys. Subcluster segregated nanoalloys consist of two separated phases, which may share a mixed interface (Fig. 11.33b, left) or may only have a small number of mixed bonds (Fig. 11.33b, right). This structure has been observed in aged Ag-Au nanoparticles synthesized via the gas aggregation method [11.118], as shown in Fig. 11.34.

Mixed Nanoalloys. This pattern may be either ordered (Fig. 11.33c, left) or random (i.e., a solid solution, Fig. 11.33c, right). Still in the case of mixed Ag-Au nanoparticles synthesized via the gas aggregation method [11.118], it is apparent that freshly produced clusters are characterized by a solid solution (random mixing) of the two elements. On the other hand, an

Fig. 11.36a,b Detailed structure of Au-Pd nanoparticles at high magnification. The high-resolution (a) and scanning TEM images (b) confirm the presence of three different layers in the domains of the core-shell structure for typical single nanoparticles. (After [11.159] with permission of ACS)

example of ordered alloy is given by PtCo nanoparticles grown on $\text{MgO}(100)$ [11.153] and observed via HR-TEM (Fig. 11.35).

Multishell Nanoalloys. Multishell nanoalloys present an onion-like structure of alternating shells of the two elements (Fig. 11.33d). An example is given by Au-Pd nanoparticles synthesized via wet chemistry methods; TEM observation highlights the presence of an internal Pd core, an intermediate Au shell, and an external Pd shell [11.159] (Fig. 11.36).

Core-Shell Segregated Nanoalloys. This pattern is formed by a shell of one type of atom (B) surrounding a core of another (A), though there may be some mixing between the shells (Fig. 11.33a). This mixing pattern is common to a large variety of systems. This is a particular case of multishell nanoalloys with only two shells.

In addition to these main ordering patterns, novel ones have also been described. An example is shown for

Fig. 11.37a–d Optimal chemical ordering in a PdPt nanoparticle of size $N_{\text{tot}} = 201$: (a) composition $\text{Pd}_{153}\text{Pt}_{48}$; (b) composition $\text{Pd}_{110}\text{Pt}_{91}$. The view represents atoms of different sizes to highlight the patchy multishell pattern in (c). Atom coloring: yellow for Pd and blue for Pt, with slightly darker shades for the inner shells. (d) The inner compositional structure of the $\text{Pd}_{110}\text{Pt}_{91}$ particle. (After [11.36] with permission of ACS)

a (Pd-Pt)₂₀₁ nanoparticle in Fig. 11.37. For this system, first-principles results for a few Pt impurities within a Pd-rich cluster unexpectedly show a marked tendency of Pt to populate the (111) surface, in agreement with coordination-dependent bond-energy variations (CBEV) predictions [11.160], but opposite to what is found in extended systems (this is thus a feature peculiar to the nanoscale). This tendency is latent at very small sizes but increases with cluster size and is clearly realized when the (111) facets are of the right size. Furthermore, a new picture emerges around composition 1 : 1. The lowest-energy chemical ordering pattern, e.g., at composition 110 : 91, is reported in Fig. 11.37, and it is clearly a multishell arrangement, but of a different kind. As can be drawn from inspection of Fig. 11.37, the structure of the fourth shell is such that Pt atoms occupy the center of surface (111) facets, whereas Pd atoms occupy the (100) facets and the edges of the surface shell. However, for the subsurface shell the chemical order is reversed with respect to that of the surface shell: Pd atoms occupy the three central positions of the (111) facets, whereas Pt occupies the (100) facets and the edges. In other words, in correspondence with

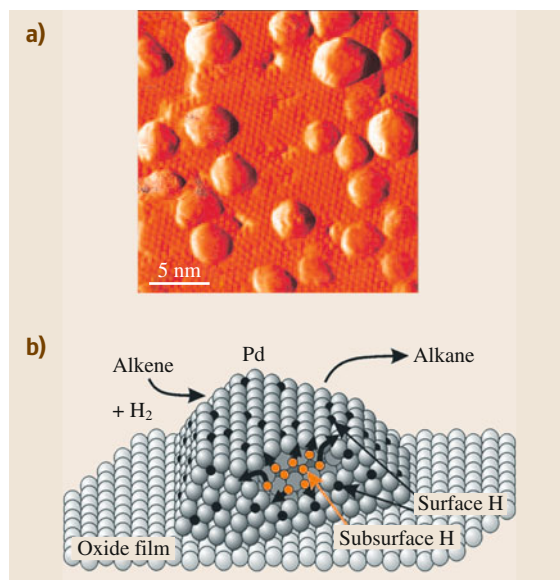

Fig. 11.38 (a) STM image of Pd nanoparticles on $\text{Fe}_3\text{O}_4(111)$. The crystallographic facets of the particles are clearly recognizable, as is the atomic corrugation of the support. (b) Schematic representation of a Pd nanoparticle indicating atomic hydrogen adsorbed on the surface and in the particle. (After [11.161] with permission of Wiley)

segregation of Pt at the center of surface facets, we find segregation of Pd at the center of the underlying facets, and so on. In this segregation pattern each shell is a patchwork of islands of atoms of the two elements, but the order of the patchwork is reversed in the alternating shells. Note that this arrangement is not bound to a precise number of atoms but is stable in a range of compositions around the equimolar one between at least 45–55% and 58–42% compositions.

Theoretical Methods for Structure Prediction

We conclude this subsection with a brief summary of the most important approaches to investigate the potential energy surface (PES) of a metallic system. Recent years have witnessed an explosive surge in the development and applications of computational science. The advances in computer science (in both software and hardware) have stimulated this surge, and a large community of computationally oriented researchers is now active in all fields of science, ranging from experimental and theoretical researchers to undergraduate and graduate students. The field of metal nanoclusters and nanoalloys is no exception to this trend: in recent years an increasing number of theoretical and computational

studies have appeared, especially dealing with predictions of the structural properties of these systems, but also extending to their magnetic, optical, and catalytic responses. Two types of approaches are traditionally distinguished: first-principles and empirical ones. In the former, one attempts to solve (at least in an approximate way) the Schrödinger equation of the system. This can be accurate and reliable, but it is computationally extremely demanding. In the latter, the system PES is expressed as an analytic function of the geometrical coordinates, depending on a set of empirical parameters that are usually fitted onto first-principles calculations or experimental data. These latter approaches are of course computationally much cheaper, and systems with thousands to millions of atoms can be easily described on nanosecond to microsecond time scales.

The problem with metal nanoparticles and nanoalloys is that they often present a fluxional character; i.e., they exhibit a rugged PES with a great number of local minima rather close in energy. They can be thus catalogued among complex systems, which are an active field of current research. To predict the structural properties of these systems, the first step consists in systematic sampling of their PES. This is usually achieved via global-optimization techniques [11.162], i.e., those computational techniques aimed at finding the absolute minimum (or global minimum) of a mathematical function. One thus selects a computational approach to evaluate the PES of the system, and then explores it via systematic searches.

The knowledge of the global minimum structure in the gas phase can obviously have limited importance when studying the behavior of metal particles in complex environments and/or undergoing dynamical processes: For example, it is recalled below that metal particles can undergo structure fluctuations and bistabilities during experiments reproducing, e.g., typical catalytic conditions. However, the output of a global optimization search is not simply the lowest-energy structure, but also a set of low-lying isomers, which are very important in determining the dynamic mechanical response of the system (e.g., during melting). Moreover, structure determination has great importance in view of *static* phenomena such as optical and magnetic properties, but even for chemical ones under mild conditions. In addition, the influence of the environment can be also introduced into the theoretical analysis. On the experimental side, recent advances allow one to characterize with a good degree of certainty the structure and morphology of metal nanoparticles and nanoalloys (see the previous section). On the theoretical side, effec-

tive tools are nowadays available to explore and predict the structural properties of metal nanoparticles, ranging from combined empirical potential/first principles global optimization algorithms to statistical-mechanics techniques with improved sampling.

The most successful computational algorithms to perform systematic sampling of the PES of nanoalloys [11.163] are based on a hierarchy of length scales; i.e., in these approaches, the choice of the theoretical modeling to be employed in performing simulations on a specific system is tuned according to its size. The idea behind these hierarchical approaches is to use for systems of different size the approach which is most efficient and also makes physical sense for each one of them.

This hierarchy is implemented in the following way. For small clusters (with number of atoms N less than a few tens, presently $N \leq 40$), it is computationally feasible to conduct global optimization using energy and forces derived from a first-principles method; see [11.164] for one of the first implementations for gas-phase metal nanoclusters (or [11.130] for a recent application), [11.165] for the first implementation for supported metal nanoclusters, and [11.166, 167] for the first implementations to (supported) alloy nanoclusters.

Aggregates with number of atoms between 40 and 200 are very interesting as they are still in the non-scalable regime in terms of electronic, magnetic, etc. properties [11.168] and at the same time novel structures are continuously being discovered in this size range, exhibiting, e.g., polytetrahedral character, hybrid combinations of close-packed and fivefold-symmetry motifs, or other exotic forms. For these aggregates it is still feasible to perform numerous first-principles calculations at various sizes using common computational resources. A full first-principles approach, however, becomes progressively less and less feasible in practice. More approximate methods such as empirical potentials must be employed. An efficient possibility is to use a combination of first-principles and empirical potential simulations [11.163].

For yet larger clusters (presently $200 \leq N \leq 1000$), even performing first-principles calculations becomes progressively infeasible, at least to conduct them in large numbers, and one has to rely entirely on global optimization searches based on empirical potential approaches. This makes sense also from a theoretical point of view, as these larger particles start to exhibit a clear metallic character and an average description of the metallic bond should be reasonable, and empirical po-

tential predictions are expected and usually found to become more and more accurate [11.169].

Finally, when a particle has more than 1000–2000 atoms, global optimization using empirical potentials becomes computationally very heavy. Moreover, empirical potentials are often overinformative. The size of the system itself in fact usually quenches structural diversity and simplifies the problem, orienting the system into a few low-energy competing motifs. It is thus meaningful and efficient to focus on these motifs and study their crossover as a function of the number of atoms, as in [11.126].

Nanoalloy Phase Diagrams

In the field of bulk metal alloys, the CALPHAD project (<http://www.calphad.org>) should be mentioned. This project, started in the early 1970s and substantiated in a scientific journal, aims at collecting and providing precise information on the thermodynamic properties of extended multicomponent systems, thus including metal alloys, in the form of accurate phase diagrams. CALPHAD in fact originally stood for *calculation of phase diagrams*. Translating this project into the field of nanostructured alloys, thus producing *size-dependent* phase diagrams, is not an easy task, but is currently being undertaken by a few groups in the scientific community, in the European context also in connection with the presently ongoing European Cooperation in Science and Technology (COST) action MP0903 (www.nanoalloy.eu).

11.4.2 Catalytic Properties

To achieve a more straightforward presentation, we focus in this subsection on heterogeneous catalysis by metal nanoparticles and nanoalloys. We thus exclude the vast field of homogeneous catalysis by coated alloy clusters, and in particular by polynuclear complexes composed of more than one metal element and by colloidal nanoalloys [11.170]. We also do not treat polymer-protected bimetallic or polymetallic nanoparticles, which are also known to be very effective and interesting systems [11.78, 79].

As recalled in Sect. 11.2, heterogeneous catalysis by metal nanoclusters and nanoalloys has been the subject of a wealth of model studies in surface science. Investigations initially focused on the reactivity of extended surfaces of pure or alloyed metals as models of nanoparticle facets [11.86–88]. In a second step, metal nanoparticles and nanoalloys rather than extended systems were grown, typically on oxide sub-

strates [11.85, 86, 89–91]. In all cases the associated simplifications of single-crystal surfaces (either for the metal or for the oxide support) and UHV conditions were employed to allow use of the sophisticated and powerful analytical tools of surface science. The use of molecular beams [11.26, 171] was greatly beneficial in these studies as it allowed quantitative and detailed investigations of the kinetics and dynamics of surface reactions. Despite the limitations associated with the pressure and materials gaps recalled above, much fundamental knowledge has been produced through such studies that would have been hardly derivable otherwise, as we show presently.

We start from the concept of descriptors of the catalytic activity of a materials system. Screening a set of possible catalysts to find the optimal one via a trial-and-error approach is an extremely demanding task, at both the experimental and theoretical levels, even though combinatorial screening can be successfully applied [11.172, 173]. Think, e.g., of all the possible binary pairs of an alloyed catalyst and all the possible different compositions. Even using computational simulations which can be faster and cheaper than performing actual experiments, one needs thorough sampling of the kinetics of a catalytic reaction, singling out local minima, reaction paths, and kinetic prefactors connecting them, which can be extremely demanding if repeated thousands of times in the search for new technical catalysts (assuming of course that such calculations are sufficiently accurate to be reliable). Some general guiding principles are in order. A viable option is to single out some descriptors determining the catalytic activity or selectivity of a catalyst [11.174]. These descriptors could be the adsorption energies of intermediates, reactants, products, or the activation energies of the rate-determining elementary steps, decided on the basis of experimental and/or theoretical results. In this perspective, surface science studies on model systems in which experimental investigations were coupled with theoretical analysis have made an important contribution to shed light on the overall picture. First of all, it has been shown that the actual choice of the descriptor may not be crucial, as some linear energy correlations between adsorption energies and activation energies, such as the Brønsted–Evans–Polanyi (BEP) relations [11.175], do seem to exist, which effectively reduce the number of independent variables for a given catalytic process. Second, it has been shown that the position of the d-band of a transition metal often correlates nicely with its chemical activity and can thus be used as a useful descriptor [11.176], although exceptions and

refinements have been recently proposed. Finally, an old principle in heterogeneous catalysis, the *Sabatier* principle [11.177], has been entirely confirmed and put on quantitative grounds. This principle states that, when trying to optimize the performance of any given catalyst, one faces as a norm conflicting requirements, i. e., the fact that if the adsorption energy of the reactants on the catalyst is too strong (or they dissociate too easily) then the successive reaction energy barriers or desorption energies will also be large, whereas vice versa if the adsorption energy is too low, then the dissociation step necessary for the catalytic activity will be difficult, so that the best compromise lies in between strong and weak energetics, and the performance of a catalyst as a function of any given descriptor will go through a maximum, leading to a *volcano* relationship between reaction rate and the energy descriptor. Using this approach, the cost of either a computational or experimental search for new catalysts can be reduced by using only a limited number of descriptors in the computational or experimental screening and locating the maximum in the volcano curve [11.174]. Clearly, given the semi-quantitative character of the knowledge derived from energy descriptors, thorough exploration of the kinetics pathway for the most promising candidates is necessary to confirm the indications derived from the preliminary analysis at the theoretical level, and eventually actual catalytic experiments are needed to validate descriptor predictions. To provide a concrete successful example, using this approach the Ni₃Fe system was proposed as an efficient methanation catalyst, and this proposal was fully confirmed by experimental tests [11.178]. Note in passing that what we have discussed so far concerns the so-called electronic structure factor in catalysis. Later we also discuss the structure factor.

To summarize this first conclusion: using descriptors taken from studies on extended surfaces, one can screen the activity of a catalyst. This is connected with the fact that in some cases extended surfaces can indeed be taken as good models of the facets of nanoparticles, and this can be used to predict, e.g., the dependence of the catalytic activity on the shape and morphology of the particles [11.179]. Another important result derived from model surface science studies is however that size effects can be very important in heterogeneous catalysis by metal nanoparticles and nanoalloys, as has been definitively proven by experiments in which carefully size-selected particles were employed [11.180, 181]. This is to be expected, as their finite size endows the nanostructures with low-coordinated sites that are absent in single-crystal surfaces of an extended (bulk)

system, and that can be beneficial or detrimental (or in some cases noninfluential) to the catalytic activity depending on its mechanistic path. An in-depth discussion is given in [11.182], in which a rationale for the distinction between structure-sensitive and structure-insensitive catalytic reactions at surfaces is advanced. In detail, in this theory three types of behavior are distinguished. In the first class of reactions, in which a π -type bond is formed or dissociated, the reactants need to have multiple contacts with several atoms from the nanoparticle surface, which is not possible below a certain particle size, whence the decrease of the catalytic activity with size. In the second class of reactions, in which a σ -type bond is dissociated in the rate-determining step such as in methane activation, the catalytic activity correlates with the ability of the catalyst particle to break strong bonds, and thus to the number of coordinatively unsaturated edge and corner atoms, which is inversely proportional to the particle size. In the third class of reactions, in which a σ -type bond is formed in the rate-determining step such as in hydrocarbon hydrogenation reactions, the catalytic activity is roughly independent of the particle size.

The view proposed in [11.182] is clearly a general and necessarily approximate one, which can be and has actually been better articulated in other studies. Even in the event that interesting reactivity occurs on smooth facets rather than at edges or corners of the particles, in fact, the greater flexibility induced by their limited size can make a difference in terms of adsorption energies and reaction energy barriers. To exemplify matters, let us consider the hydrogenation of *cis*-2-butene on Pd nanoparticles (Fig. 11.38). In a series of studies [11.161, 183] it has been shown that:

- Pd nanoparticles of 4–5 nm size supported on a Fe₃O₄ support are good models of the corresponding technical hydrogenation catalysts, whereas this does not hold for extended Pd(111) single-crystal surfaces, which are catalytically much more inert.
- The catalytic activity of the Pd nanoparticles is strongly connected with the presence of subsurface hydrogen atoms.
- These subsurface atoms are much more abundant on a (111) facets of a supported nanoparticle than on an extended (111) surface, due to: (1) the greater structural freedom of the nanoparticle, which better accommodates subsurface hydrogen and carbonaceous species which promote H diffusivity, and (2) the finite size of the nanoparticles with the presence of an underlying support which confines

hydrogen closer to the surface. In short, in this case extended surfaces do not make a good modeling job. However, in this and similar cases, they may be used to model the catalytic process if properly mimicking finite-size effects by considering stepped surfaces, i. e., by bridging the so-called *structure gap*, that is, the greater structural flexibility of confined facets with respect to extended systems [11.184]. The importance of local defectivity and structural relaxation on the catalytic activity of metal nanosystems has been also proved in detailed investigations of the catalytic activity of Cu nanoparticles in methanol steam reforming [11.185, 186], in which it has been shown that the catalytic activity correlates not only with the decreasing particle size but also with the local microstrain and structural disorder. These investigations have brought about not only new knowledge, but also practical advantages, as they have led to improving by a factor of 2 the activity of technical catalysts. It should also be mentioned that, for full understanding of the kinetics of catalytic reactions on nanoscale particles, coverage fluctuations and microkinetic models also have a crucial influence according to recent contentions [11.187].

These results point to the importance of the status of the catalyst surface under reaction conditions, with the possibility, e.g., of forming surface alloys or ligand-induced reconstructions or intermetallic compounds [11.188], and some of the knowledge derived from model studies relevant for catalysis concerns this topic: For example, an important effect that can be drawn even from model studies at low pressures and that has been further confirmed by investigations at more realistic pressures is the possibility of particle restructuring and reshaping under reaction conditions. Adsorption of reactant molecules in fact modifies the relative energetics of the different facets of the nanoparticles, and thus – as a consequence of the Wulff construction – can give rise to substantial changes in the particle morphology, as observed experimentally [11.189] in fair agreement with theoretical predictions, e.g., the study in [11.181]. To summarize, one typically expects that more open facets, such as (100) with respect to (111), will be more reactive and therefore more stabilized by the interaction with, e.g., oxygen species, so that they will grow in oxidative conditions at the expense of the more inert ones; a simple example is given in Fig. 11.39, but more complicated ones with more extensive faceting can be also expected on general terms [11.190].

Fig. 11.39a–c Morphology of supported silver particles in case of (a) nonoxidized surfaces, and oxygen-covered surfaces at (b) $p(\text{O}_2) = 5 \times 10^{-3}$ atm and (c) $p(\text{O}_2) = 1$ atm. The lateral dimension of the clusters is about 6 nm. (After [11.181] with permission of Elsevier)

The precise chemical status of the surface of the nanoparticles is important also in view of the ongoing debate concerning whether the active catalysts in oxidation reactions are the metal nanoparticles themselves or rather the corresponding metal oxide particles generated by their preliminary oxidation under reaction conditions. Recent findings, e.g., on the CO oxidation reaction catalyzed by Pd nanoparticles of ≈ 5 nm diameter supported on $\gamma\text{-Al}_2\text{O}_3$ [11.191], seem to indicate that under oxygen pressure the surface of the particle is indeed covered by oxygen species as in analogous oxidation catalysts [11.181], but that substoichiometric $\text{PdO}_{x < 1}$ species can be rapidly reduced by CO to Pd^0 , so that they exhibit a comparable CO oxidation activity, whereas stoichiometric PdO nanoparticles show lower catalytic activity due to their greater stability and more difficult reduction by CO. In other words, the active phase present under the current reaction conditions seems to be oxygen-covered – and thus appreciably modified – metallic Pd particles.

Size effects and low-coordinated atoms, which have been mentioned above, are especially important for those metals that have been traditionally thought of as catalytically inert, but that acquire a rich, fascinating, and unexpected catalytic activity when forged at the nanoscale, as has been proved for gold [11.192–197]. Indeed, there is recent experimental evidence that the real actors of CO oxidation by Au nanoclusters are subnanometer species containing ≈ 10 Au atoms [11.198]. This leads us to the field of extremely small particles, a somewhat novel field, despite the fact that the possibility of the importance of very small metal clusters in catalysis was advanced long ago [11.22], as supported by EXAFS evidence [11.199].

At one extreme of size effects, one finds in fact the catalysis by extremely small or subnanometer clusters, i. e., pure or alloyed metal clusters containing fewer than, say, 20 atoms and thus with size of the order of

1 nm or less. Clearly, in such species the metallic bond is only partially developed, and they exhibit molecule-like rather than conductive behavior. Still, they belong to the class of metal nanoclusters and nanoalloys, are very interesting materials, and often possess catalytic properties which are very different and sometimes more interesting than their extended analogs [11.200]. Finite-size effects are here in the extremely non-scalable regime in which adding or removing a single atom from the cluster may lead to dramatic changes in catalytic performance. In addition, the effect of the support is here crucial, and it has been shown for example both experimentally and theoretically that even a simple ionic oxide support can transform inert species such as Ag_3 or Au_3 into efficient oxidation catalysts [11.200, 201]. Also, in such clusters it does not make much sense to talk about facets and the link to extended systems become questionable. Corners and edges dominate the morphology of these systems, and descriptors that have been developed for bulk surfaces may not be useful here and new descriptors may need to be developed (an interesting example in this direction is given in [11.202]). From the theoretical point of view, subnanometer metal heterogeneous catalysts are particularly interesting because they offer the chance to exploit recent methodological advances in the computational sampling of rugged potential energy surfaces, as recently proposed [11.201]. An especially interesting effects that can be simulated via these theoretical approaches and compared with experiment, and whose validity probably exceeds the field of subnanometer clusters, is disruption of catalyst particles induced by ligands and reactants and their reformation to achieve a dynamic equilibrium [11.203]. This is also connected with the phenomenon of Ostwald ripening or sintering [11.204], i.e., the disappearance of small metal clusters in favor of larger aggregates. Without entering into the details of this complex phenomenon, it can be observed that it is an experimental observation supported by theoretical simulations that the presence of CO but also especially the coadsorption of CO and O_2 can weaken metal-metal bonds and lead to cluster disgregation [11.201, 205]. To summarize, subnanometer metal cluster and alloy catalysts represent a field in vigorous expansion, in which further surprises can be expected in the near future.

Coming now to the field of nanoalloys (which is the topic of the present chapter), in addition to the concepts discussed above and valid for both pure and mixed nanoparticles, some new, specific features arise.

The first point concerns the structural properties discussed in the previous subsection. In general, when

studying a bi- or multicomponent nanosystem, it must first be ascertained whether the two (or more) elements form some kind of alloys or remain as separated pure nanoparticles. Second, it should also be known whether the chemical composition is the same over all particles, i.e., the dispersion of the composition. Third, one should ascertain which structure is generated by alloying, as we have shown above that even minor amounts of a second element can completely change the dominant structural motifs of the particles. Fourth, once the structural framework is clear, it should be determined which kind of chemical ordering is realized on this framework. Regarding the latter issue, i.e., the crux of nanoalloys, namely chemical ordering, it must be recalled that, given a certain chemical ordering, e.g., with segregation of one component to the surface, the presence of ligands and reactants can entail reversal of such segregation under catalytic conditions [11.32]. This phenomenon, which is probably a ubiquitous one [11.206], is due to the fact that the surface energies of the metal can be strongly affected by the interaction with exogenous species [11.207], so much as to fully revert their relative ordering and thus produce a segregation inversion under reaction conditions (see the discussion on restructuring and reshaping above). Indeed, Ni reversed segregation at the surface of Au-Ni particles under oxygen and Pd reversed segregation at the surface of Ag-Pd particles under CO have long been suggested on the basis of chemisorption [11.22] or EXAFS [11.208] data.

The second point concerns the discussion of the effects of alloying on the activity of the nanocatalysts (or *bimetallic* or *polymetallic cluster catalysts*, as they were once called). These effects have been traditionally distinguished into two types: structural and electronic [11.22].

Electronic effects on the chemical properties of a binary metal system have long been proposed in the search for improved catalysts [11.22, 209], assuming intimate mixing of the two species: For example, charge transfer [11.210] was suggested to have an important influence on surface metal-metal bonds that involve dissimilar elements, so that the cohesive energy of a bimetallic bond correlates with the flow of electron density toward the element with the larger fraction of empty states in its valence band, and it was pointed out that this phenomenon is realized at a surface in a very different way from what occurs in bulk alloys, thus entailing a strong dependence on the structural geometry of the bimetallic system. Charge transfer effects have been investigated again at the

first-principles level, and their importance in determining structural properties confirmed on more realistic Ag-Au nanoparticles [11.137], also proposing a way to efficiently account for such effects within empirical potentials [11.211]. More recently, it can be noted that the descriptor approach discussed above to screen a set of possible catalysts in the search for the optimal one [11.174] is essentially based on the investigation of electronic effects due to alloying, and we have already recalled that this approach was successful in singling out an efficient novel methanation catalyst [11.178]. It should be added in this connection that an inverse correlation was observed concerning electronic effects due to alloying: in other words, if alloying element A with B increases the interaction energy with a ligand species, then one should expect that alloying B with A decreases the interaction energy of B with the same species [11.207].

As for structural effects due to alloying, still assuming intimate mixing of the two species, the hypothesis that the structure, through the surface composition, of *bimetallic cluster catalysts* can appreciably influence their selectivity dates back to several decades ago [11.22]. Cu segregation at the surface of both Cu-Ni and Cu-Ru particles were hypothesized on the basis of hydrogen chemisorption data, and used to explain the decreased activity of Cu-Ni particles in ethane hydrogenolysis [11.22, 140] via a mechanism similar to that in which a π -type bond is formed or dissociated discussed above [11.182]. Analogously, the much higher selectivity of Cu-Ru particles with respect to pure Ru ones in orienting the dehydrogenation of cyclohexane into benzene rather than its hydrogenolysis into methane was rationalized by invoking that hydrogenolysis needed a multiplet of Ru centers and was therefore hampered by Cu alloying and surface segregation, whereas dehydrogenation went through a mechanism similar to that in which a σ -type bond is formed in the rate-determining step discussed above [11.182], and was therefore structure and alloying insensitive (also being insensitive to electronic structure and the electronic structure due to alloying).

In more recent work the activity of Cr-Pt nanoalloys with respect to oxygen reduction reaction was studied [11.212], and it was shown that only when an ordered CrPt₃ alloy phase was formed throughout the particle (not only at the surface) was a substantial enhancement by 2–3.5 times of the catalytic activity achieved. In this case, such an enhancement was connected with a structural effect: the reduction in the Pt–Pt distances due to thorough mixing with Cr.

Other alloying effects on nanocatalysis are easier to explain and predict. Going to the nanoscale is known to be advantageous from an economic point of view even in the absence of other benefits as it increases the surface-to-bulk composition ratio, which – given that catalysis is dominated by processes occurring at surface atoms – increases the activity per atom of nanosystems. A merely economic gain can correspondingly be obtained in multicomponent systems even under the hypothesis that there is no structural or electronic effect due to alloying, supposing for example production of a core–shell particle in which a catalytically inert, inexpensive element fills the particle core, while the catalytically active precious one segregates at the surface; such systems are therefore called *atomically economical*. Other effects are simply due to the synergy of having a multifunctional catalyst, i. e., a system simultaneously containing two or more active species, each of which realizes a different and specific function, as for Pt and Ru sites in CO oxidation [11.213] or Cu and Pd sites in electrocatalytic reduction of NO₃[−] [11.214]. In such cases the catalytic system could in principle work also in the presence of strong segregation or spatial separation of the two components. However, the proximity in space of the two catalytically active species can facilitate mass transport phenomena which are sometimes essential to achieve efficient catalysis.

An electronic effect has also been suggested for the promotional role of Au in Au-Pd nanoparticles with Au (core)–Pd (shell) chemical ordering [11.215, 216], even though theoretical analysis does not predict an important electronic effect for this binary pair [11.207]. Later investigations in fact showed that the core–shell ordering is not essential for the observation of high reaction rates and selectivity, which are also obtained when Au and Pd are homogeneously mixed [11.206]. The true origin of this synergic effect is thus still unknown. Another very interesting example is provided by Ag-Au nanoparticles, which have been recently shown to be both more stable and more active to promote CO oxidation than either Au or Ag pure particles [11.217], although it is not yet fully clear whether this improvement is due to electronic or structural effects. Many other examples exist in which one finds a substantial improvement of the activity and/or selectivity of a catalyst due to alloying, which have not yet been rationalized. As an interesting and most recent example, we mention the aerobic oxidation of allyl alcohol to 3-hydroxypropionic acid by carbon-supported Au nanoparticles when even a minor amount ($\approx 1\%$) of Cu is added [11.218].

Now focusing attention briefly on the topic of heterogeneous catalysis by extremely small or subnanometer clusters, discussed above for pure systems, it should be noted that the related knowledge is scarce (the situation is different in the field of homogeneous catalysis, in which polynuclear multicomponent organometallic complexes have been studied). In one of the pioneering examples [11.219] Ru_5PtSn and Ru_4Sn_2 species grafted on mesoporous silica were shown to exhibit exceptional activities and selectivities in hydrogenation reactions at lower temperatures and pressures than those used in industrial processes. Very recently, a positive effect of alloying on the catalytic properties of subnanometer clusters has been proposed [11.201], in which $(\text{Ag-Au})_3$ binary clusters were predicted via first-principles simulations to possess improved features with respect to Ag_3 or Au_3 pure clusters in partial oxidation reactions.

We conclude this subsection with a few considerations on theory and simulations of catalysis by nanoalloys. Due to the difficulties of in situ experimental characterization (despite the notable recent advances in this direction reviewed in Sect. 11.3), the possibility of realizing *thought experiments* or *computational experiments* and deriving with often sufficient accuracy quantities that are hardly measurable at the experimental level has made such theory and simulations play a very important role in this field. We have recalled the computational screening of novel catalysts [11.174], and in general the successes of theory in predicting novel catalysts [11.178] or in rationalizing reaction mechanisms [11.185, 186]. We have also underlined that, in order to be fully predictive, complete computational modeling needs thorough sampling of the kinetics of a catalytic reaction, singling out local minima, reaction paths, and kinetic prefactors connecting them, which is an extremely demanding task. Recent methodological advances in computational sampling of rugged potential energy surfaces [11.201] have made this task already achievable for subnanometer metal clusters. However, this is probably still not sufficient if one aims to describe at a computational level in a predictive way extremely complex systems such as fuel cells. These involve modeling of electrocatalysts, proton conducting membrane, reactants, and interfaces between them, something that probably will not be realizable at the first-principles level only for many years to come. A possible solution lies in multiscale algorithms [11.221] in which quantum-mechanical simulations are at some point replaced by classical ones employing empirical potentials or force fields, or even

higher levels of length and time rescaling. In this context, reactive force fields [11.222] are necessary, given the chemical transformations with bond rupture and formation which are at the basis of catalysis. All this lies at the forefront of current research.

11.4.3 Optical Properties

The optical properties of metal nanoparticles and nanoalloys are a subject of great interest from the points of view of both basic science and technological applications [11.3]. The reasons for this interest lie first of all in the main feature of the optical response of simple or noble metal nanoclusters to excitation by light, which is a strong absorption band in the UV-Visible range related to the surface plasmonic resonance (SPR), i.e., a coherent and collective oscillation of the electrons involved in the metallic bonds in confined systems subjected to electromagnetic radiation of proper wavelength. Plasmons (Fig. 11.40) are thus collective oscillations of conduction electrons in metals. As recalled in previous sections, the use of metal nanoclusters as light absorbers has been unknowingly employed by humanity for thousands of years. The association of this effect with the presence of metal nanoparticles was however first recognized by Faraday only in 1857 [11.8], and theoretically explained by Mie in 1908 [11.223].

A second feature that makes metal nanoparticles attractive in optical studies is the fact that their electronic structure and consequently their optical response are sensitive to structural parameters such as size, shape, and – for multicomponent systems – composition and chemical ordering, in addition to the dielectric environment, so that they can be tuned with great freedom.

A third important point is that plasmonic resonances of nearby nanosystems can interact with each other via electromagnetic coupling, providing an effective way

Fig. 11.40 Schematic diagrams illustrating a localized surface plasmon. (After [11.220] Annual Reviews)

of manipulating light at the nanoscale and giving rise to a wealth of phenomena going under the heading of *plasmonics*.

The coupling of the electromagnetic fields at the surface of the particles (possibly amplified by plasmonics effects) with optical excitation of other neighboring species can then be exploited in the so-called surface-enhanced spectroscopies [11.6], such as surface-enhanced Raman scattering (SERS) and surface-enhanced infrared absorption (SEIRA), which are very important and extremely promising, e.g., in biomedical applications.

Experimental studies in this area thus include synthetic techniques, spectroscopic studies of the particle properties and of molecules on the particles, and the development of applications, such as detection of single molecules and enhancing optical absorption in solar energy conversion devices. From the theoretical point of view, the efficient extension of electromagnetic calculations to the complex systems present in *plasmonic materials* and the inclusion of quantum effects especially when molecules at the surface of the particles are investigated should be mentioned.

It is important to mention that in 2011 an entire issue of *Chemical Reviews* [11.224] as well as virtual issues of the *Journal of Physical Chemistry* [11.225] and of *ACS Nano* [11.226] were dedicated to plasmonics. The optical properties of metal nanoparticles are also treated in Chap. 9 by Pradeep, while their application in nanomedicine are treated in Chap. 30 by Letfullin et al. in this handbook. Our presentation will therefore be necessarily contained to avoid excessive overlap with these excellent reference works.

We begin by briefly recalling Mie theory [11.3] to provide some basic knowledge as a starting point. This theory, based on the classical Maxwell equations, applies to a spherical particle interacting with a plane electromagnetic wave and solves these equations by imposing appropriate boundary conditions. The main result for a particle for which the dipolar approximation is valid (i.e., whose size is much smaller than the wavelength of the radiation) is that the extinction cross-section reads

$$\sigma(\omega) = \frac{9 \left(\frac{\omega}{c}\right) (\varepsilon_m)^{\frac{3}{2}} \varepsilon_2(\omega)}{\{[\varepsilon_1(\omega) + 2\varepsilon_m]^2 + \varepsilon_2(\omega)^2\}} V_0, \quad (11.2)$$

where V_0 is the particle volume, ε_m the dielectric constant of the surrounding medium, and $\varepsilon_1(\omega)$ and $\varepsilon_2(\omega)$ are the real and imaginary part of the dielectric function of the particle, respectively. The maximum in $\sigma(\omega)$ occurs when the denominator of the fraction in (11.2)

is minimized, which – in the hypothesis of neglecting $\varepsilon_2(\omega)$ (justified for simple metals, less so for noble ones) – corresponds to the condition $\varepsilon_1(\omega) = -2\varepsilon_m$. If one uses a model of a simple electron gas (Drude model) to estimate $\varepsilon_1(\omega)$ and $\varepsilon_2(\omega)$, one finds

$$\varepsilon_1(\omega) = 1 - \left(\frac{\omega_p}{\omega}\right)^2, \\ \varepsilon_2(\omega) = \left(\frac{\Gamma}{\omega}\right) \left(\frac{\omega_p}{\omega}\right)^2,$$

where ω_p is the frequency of the plasmon resonance in the bulk and Γ is a damping constant that takes into account electron–phonon and other intrinsic electron relaxation mechanism. This translates into an extinction cross-section with adsorption peak of Lorentzian shape centered at $\omega_1 = \omega_p/(1 + 2\varepsilon_m)^{1/2}$ and of width equal to $\Gamma/2$.

Several points are worth mentioning: first, the proportionality of the cross-section to the particle volume, which entails a cubic dependence on its diameter; second, the weak dependence of the position of the peak (ω_1) on the particle size, entering only via the dependence of $\varepsilon_1(\omega)$ and $\varepsilon_2(\omega)$ such that a slight red-shift is observed for larger particles (Fig. 11.41); third, the fact that the damping constant is instead appreciably sensitive to the particle size: for small particles (less than, say, 20 nm in diameter) Γ increases with decreasing particle size as contributions from scattering of conduction electrons from the particle surface become important [11.63]; for larger particles, instead, higher-order terms than the dipole start contributing and the finite particle size produces depolarization and radiative contributions which broaden and eventually wash out plasmon resonance effects [11.227].

From the point of view of Mie's theory, all metal nanoparticles should in principle give rise to a plasmon peak, as all metals have mobile and polarizable conduction-band electrons. This is indeed experimentally verified for simple and noble metals. For transition metals, however, the plasmonic response of conduction (s-type) electrons is strongly damped by the coupling with d-band electrons, to such an extent that it has a minor importance in applications. Also, the smaller chemical activity and greater inertness of noble metals as compared with simple metals such as the alkali ones (even though at the nanoscale also noble metals can exhibit an important catalytic activity, see Sect. 11.4.2) entails that in practice only Cu, Ag, and Au are usually considered in plasmonics applications. With respect to Ag and Cu, Au presents s-orbitals which are more localized due to the so-called relativistic contraction [11.228]

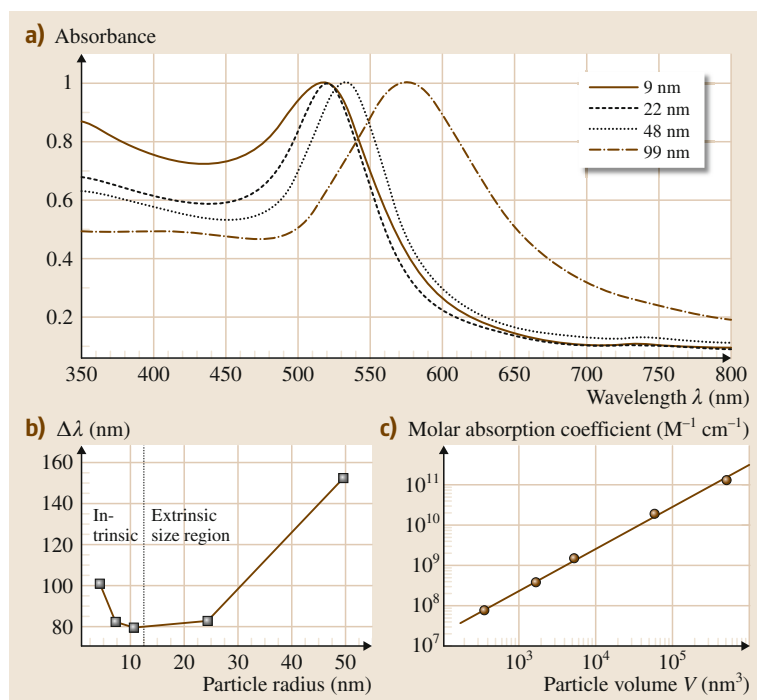

Fig. 11.41a–c Size effects on the surface plasmon absorption of spherical gold nanoparticles. The UV-Vis absorption spectra of colloidal solutions of gold nanoparticles with diameters varying between 9 and 99 nm show that the absorption maximum red-shifts with increasing particle size in (a), while the plasmon bandwidth follows the behavior illustrated in (b). The bandwidth increases with decreasing nanoparticle radius in the intrinsic size region and also with increasing radius in the extrinsic size region as predicted by theory. In (c) the extinction coefficients of these gold nanoparticles at their respective plasmon absorption maxima are plotted against their volume on a double logarithmic scale. The solid line is a linear fit of the data points, illustrating that a linear dependence is observed, in agreement with Mie theory. (After [11.63] with permission of ACS)

and interact appreciably with 5d electrons (despite the fact that the 5d band is formally full), and this relatively attenuates the plasmonic response of Au nanoparticles. In short, electrons in silver clusters behave more like a free electron gas, giving rise to well-defined, intense and sharp plasmonic features, while in gold clusters interband transitions somewhat decrease effects such as intensity and sensitivity to shape.

The Mie solution for a single spherical particle is analytic as shown above. For more complicated systems, a very common approach is the discrete dipole approximation (DDA) in which the metal system is described in terms of an array of polarizable elements whose polarizabilities are determined by the metal dielectric function [11.229] and the corresponding coupled equations are solved self-consistently. For systems up to a few hundred nanometers in size, these equations can be solved with reasonable computational effort, thus allowing one to predict the optical spectra of unusual shapes such as tetrahedra, disks, ensembles of particles, etc. using available software [11.230]. Alternative approaches solve the Maxwell equations via finite-difference or finite-element methods [11.229]. These studies have shown that a great variety of behavior can be obtained and that the plasmon peak can be freely manipulated by choosing the right geometrical

configuration [11.231–234]. One major point to be recalled is that the optical spectrum of elongated systems, such as nanorods or nanowires, presents both transverse and longitudinal absorption peaks [11.63, 235], and that the latter are strongly red-shifted with respect to comparable spherical systems [11.236]. Shape manipulation is thus an effective way of modulating the position and the width of the SPR of a nanosystem with great freedom.

These electrodynamic models are thus appropriate and can be accurate for not so small, single-component structures [11.6, 237]. Rigorous data are however still partly lacking for small metal nanoparticles a few nanometers in size and for more complicated cases such as multicomponent metallic nanoparticles or nanoalloys. The finite size of the particles can be taken into account in electrodynamic models by introducing nonlocal effects into the particle dielectric function [11.238], but this extension presents some ambiguities and it is not yet clear whether it can provide a real advantage with respect to the original theory. First-principles approaches, in particular those based on time-dependent density-functional theory (TDDFT) [11.6, 239, 240], could give a rigorous answer for these more complicated cases, if the issue of the computational effort rapidly increasing with system

size is solved. A reasonable starting point along this line is to consider a so-called jellium model, i.e., a model in which the confining complicated potential due to the atoms is replaced by a constant potential background. In other words, attention is limited to conduction electrons moving in a simplified external potential with an idealized spatial behavior; for example, a nanoparticle can be modeled by a potential which is constant within a sphere of given radius and zero outside it. The number of electrons corresponds to the given density, while the value of the constant is a parameter which is adjusted to reproduce, e.g., the work function of the particle [11.241–244]. The simplifications in the jellium model allow one to conduct calculations on systems containing hundreds of thousands electrons, and have shown that classical electrodynamics normally does a good job in predicting the position of plasmon resonances for not so small nanostructures, but is obviously much less accurate in predicting their width and fine details such as field enhancements in close proximity to the particle surface. The next step is to consider a higher level in which a fully atomistic description of the nanosystems is used and TDDFT calculations are conducted in which in principle all the electrons of the particles, both conduction and valence, and a full description of the nuclei are employed. Such calculations have been performed in the literature on small metal clusters (see as one example [11.245]) but unfortunately rapidly become unfeasible for larger systems. The computational effort of atomistically detailed TDDFT calculations in fact increases so rapidly with the size of the system that one needs to push this approach to its present limits to produce results on clusters of experimentally and physically interesting size. As mentioned in a previous section, an effective tool to enlarge as much as possible the size of computationally affordable systems is then to consider high-symmetry magic clusters [11.24, 36, 246–251]. The exploitation of symmetry (with high-order point groups such as Oh or Ih) reduces by orders of magnitude the computational effort, as the electronic excitations which make up the optical response can be catalogued into appropriate irreducible representations of the symmetry group, and the interactions among excitations belonging to irreducible representations not coupled by the perturbation operator are automatically null by symmetry. As of now, the size range of around 200 atoms is about the maximum that can be confidently treated when studying linear optical response using current computational resources even with full exploitation of point group symmetry, but future developments can probably double this size

limit in the near future. Anyway, clusters of 150–200 atoms are large enough to start observing a resonance peak that will lead to the SPR. Using this approach, the optical properties of Au nanoclusters in the size range around 150–170 atoms were studied as a function of the approximation used for the DFT exchange–correlation (xc) functional and the shape or morphology of the nanocluster [11.250]. From this study, it resulted that the position of the peak in the absorption spectrum was weakly dependent on the shape of the Au cluster but was essentially related to its size and to the DFT methodology (xc-functional) used in the calculations, and that the predictions of the van Leeuwen–Baerends (LB94) xc-functional compared better with the available experimental data with respect to those of the local density approximation (LDA) xc-functional, once corrections for the environment were properly accounted for. The main results of this work are shown in Fig. 11.42.

Clearly, for the reasons mentioned above, interband transitions damp the sensitivity of the optical response of Au nanoclusters to shape, especially for sphere-like configurations such as those considered in [11.250].

Let us now come to a topic more strictly connected with the subject of the present chapter and discuss the effects of alloying on the optical response of metal nanoparticles. Let us consider for example the most thoroughly investigated case, namely that of Ag-Au alloyed nanoparticles [11.63, 252–254]. At the experimental level [11.63, 254], what is observed when alloying Ag and Au in nanoparticles of essentially spherical shape is that the plasmonic peak shifts to higher energies, becomes relatively narrower, and gains in intensity on increasing the Ag concentration from pure Au to pure Ag cluster (Fig. 11.43a). In a classical electrodynamics calculation or even within the jellium model the atomistic details of the systems are basically lost, and one has to resort to some sort of averaged description; i.e., one needs to define an effective dielectric function or an effective potential which is constant throughout the particle in the case of homogeneously alloyed systems or stepwise constant in the case of segregated systems. The problem is that it is not clear how to define these quantities without reference to experimental results. In other words, the extent of the interplay between local and collective electronic states in interatomic metallic bonding as a function of composition and of the distribution of the atomic species within the particle is scarcely known. To answer the consequent need for rigorous information and respond to some basic questions still existing in this field (e.g., the exact dependence of the shape and peak

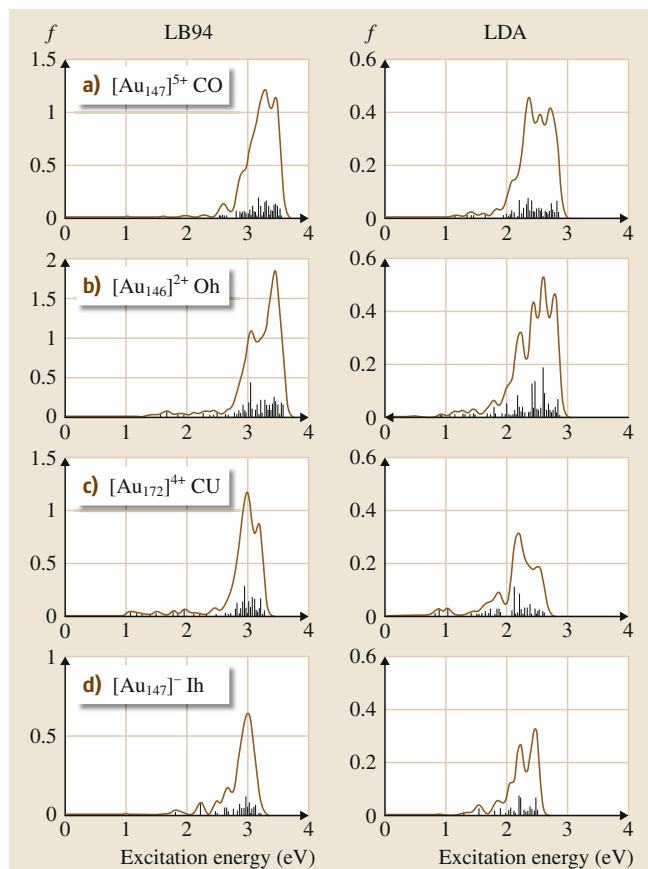

Fig. 11.42 Photoabsorption spectra simulated via a TDDFT approach at the LB94 and LDA level for Au nanoclusters at LDA-relaxed geometries: CO = cuboctahedron, Oh = octahedron, CU = cube, Ih = icosahedron. (After [11.250] with permission of ACS)

of SPR upon nanoparticle composition and chemical ordering), TDDFT calculations with fully atomistic description can make a decisive contribution. Again, the use of magic clusters is crucial to decrease the computational effort of atomistic TDDFT to a manageable size. In the case of nanoalloys, exploitation of symmetry has another great advantage. In addition to structural morphology and chemical composition, in fact, chemical ordering can play a role in nanoalloys, but thorough sampling of the chemical ordering degrees of freedom is not feasible with present computational facilities, not even for particles of around 150 atoms. As mentioned earlier, the high symmetry assured by magic structures is particularly convenient for nanoalloys, as it can be exploited not only to reduce the computational effort

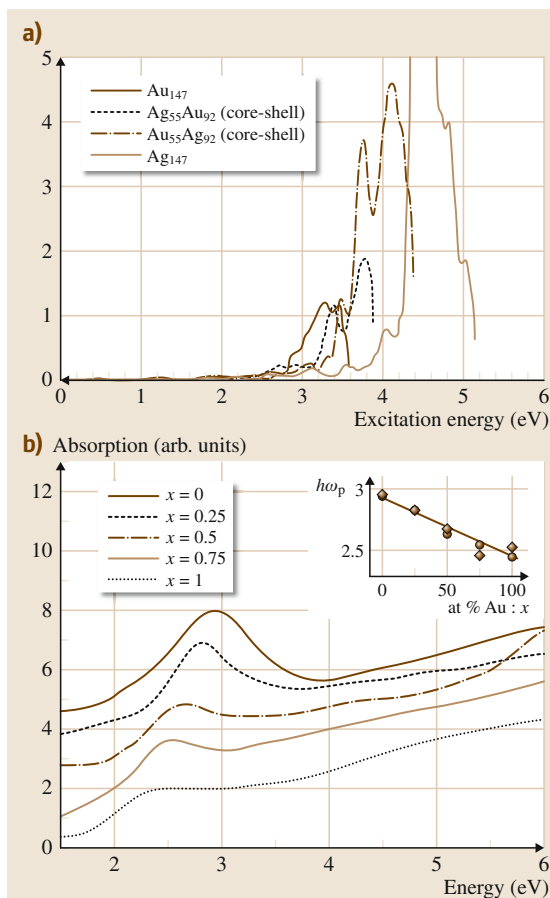

Fig. 11.43a,b Photoabsorption spectra of cuboctahedral bimetallic clusters with increasing silver concentration. (a) Calculated TDDFT LB94 spectra; (b) experimental spectra. (After [11.251] with permission of ACS)

but also to partition the atoms into symmetry shells or orbits, i.e., groups of symmetry-equivalent species (which are converted into one another by the operations of the symmetry group). This exponentially reduces the configurational degrees of freedom of the system, making sampling of the nanoalloy configurational phase space feasible via first-principles simulations even for medium-sized particles [11.24, 36]. This magic-cluster approach was applied in recent work to pure Ag and mixed Ag-Au nanoclusters of size around 150 atoms, focusing on the effect of alloying on the optical response of these systems [11.251]. It was found that the absorption spectrum of Ag clusters is more sensitive to the particle shape than that of Au clusters, as expected on the basis of a smaller damping due to interband

transitions, that configurations with rather different chemical ordering (such as core-shell versus intermixed ones) present spectra with similar position and intensity but different shape, and that the plasmonic peak shifts to higher energies, becomes relatively narrower, and gains in intensity on increasing the Ag concentration in the cluster. The behavior of the nanoalloy plasmon peak with composition can be understood by thinking that, after all, Ag and Au are quite similar, except in the extent of the coupling among s- and d-states which damps and broadens the plasmon peak for Au systems, so that when mixing the two metals a progressive transformation of one's spectral features into the other one's occurs. An example of the kind of agreement that can be obtained between theory and available experimental information is shown in Fig. 11.43 [11.251], where it should be taken into account for a proper comparison between theory and experiment that experimental spectra are shifted at lower energy with respect to gas-phase systems due to environmental (matrix) effects [11.255]. This good agreement opens promising perspectives for applications also in view of the possibility of investigating more complicated systems such as those presenting chiral [11.6, 256–258] and magneto-optical effects [11.15].

The minor dependence of the plasmon resonance upon chemical ordering found in [11.251], such that only a slight difference was observed between core-shell and fully mixed configurations, is possibly due to the limited size of the clusters which were considered in this work due to computational limitations. Let us take for example the case of Au-Pt particles. One should expect a significant difference in the optical response of these systems between core-shell and fully mixed configurations, as in the former one has a Au shell which should be optically active and somewhat decoupled from the optically inert Pt core, whereas in the latter the strong mixing of Au and Pt states might lead to the disappearance of the plasmon peak. Indeed, a similar scenario was hypothesized in the literature [11.259] and can be invoked to rationalize other experimental results [11.260] also on similar systems [11.253] (see also below), especially in connection with a slow dynamics of chemical ordering in specific nanoalloys. Further studies are needed to confirm and validate these expectations.

For future perspectives of a more detailed and thorough comparison between theory and experiment, it should be mentioned that one of the topics of current research is realization of measurements on a single nanoparticle [11.10, 236]. This allows one to disen-

tangle all the convolution effects due to particle size dispersion and furnish much more detailed experimental information. It should also be mentioned that the data reported in the right-hand side of Fig. 11.43 were conducted on particles embedded in a matrix, but the general principles here outlined should also apply to particles coated by surfactants and organic or biological ligands. In this respect and focusing on the case of very small particles (containing up to 200 atoms), an interesting recent alternative proceeds via the preparation of size-selected coated clusters, specifically of gold. This has been achieved via synthetic routes which exploit the magic character and thus the increased chemical stability of some of these clusters at specific numbers: 25, 38, 144, ... [11.6, 58, 59]. Further developments have led to the synthesis of the same clusters but in which alloyed Ag-Au rather than pure Au systems were prepared, and to their accurate optical characterization [11.261]. It is interesting to observe that at these very small sizes one can find a fragmentation of the spectrum due to quantum size effects [11.262], which is predicted theoretically (Fig. 11.43b) and has been confirmed experimentally [11.261]. On the theoretical side, so far the optical spectra of these magic systems have been simulated via TDDFT only for the smallest sizes [11.263], revealing good agreement with experiment, but it is likely that the lack of simulations for the larger sizes will be filled in the near future.

One fascinating field of research is that of interacting plasmons, i.e., interactions between strongly coupled metallic nanostructures [11.5, 264]. By properly tailoring these interactions by playing with geometrical parameters it has been shown that it is possible to control electromagnetic radiation at the nanoscale, thus enabling a variety of possible applications: For example, if the coupling of two nearby oscillators is sufficiently strong, their resonant frequencies can be shifted, resulting in new red-shifted and blue-shifted resonances with respect to the original nanoparticle signals. Also, the junction between adjacent nanostructures can give rise to highly intense and localized electromagnetic fields when excited by incident light of the appropriate polarization (so-called *hot spots*) which can be effectively used to enhance the optical spectra of adsorbed or adjacent molecules by many orders of magnitude such as in surface-enhanced Raman scattering (SERS) and surface-enhanced infrared absorption (SEIRA). This is extremely important in order to achieve the single-molecule detection limit [11.265]. These effects can enhance not only absorption spectroscopies, but also fluorescence ones; an interesting

example can be found in [11.266, 267]. Plasmon systems that are strongly coupled because of their close proximity cannot be described by classical electrodynamics, as quantum-mechanical processes such as tunneling start dominating their optical properties. Moreover, complex systems of coupled plasmons can also exhibit coherence effects, such as Fano resonances, which can be used to modify the properties of plasmonic media [11.5, 268]. Clearly, all these fascinating developments will require significant advances in quantum modeling for their deep understanding.

Most of this research on interacting plasmons is not specific to nanoalloys. In this context, nanoalloys can be useful to tune the properties of the single plasmonic unit, as shown above. Other intriguing possibilities, such as hybrid core-shell nanostructures in which both the core and the shell exhibit a plasmonic response which can interact between themselves, have been less considered in the literature, even though they can be important, e.g., in Förster resonance energy transfer (FRET) [11.269, 270]. Also, nonlinear optical properties represent a fascinating topic which is outside the scope of this chapter [11.271–273].

As a link to the next subsection, we can briefly introduce magneto-optical properties of metal nanoclusters [11.15]. This is an exciting field of research aimed at preparing and investigating multifunctional nanostructures exhibiting both magnetic and plasmonic properties [11.274–276]. To focus on a specific example, let us consider Au-Fe nanoparticles at roughly equimolar composition obtained as solid-solution (random) nanoalloys (with a somewhat broad distribution centered around 4–6 nm diameter) implanted in a SiO₂ matrix [11.260]. Experimentally, it was shown that in such Au-Fe nanoparticles, strong hybridization of Au and Fe electronic states occurs, producing a decrease in the magnetic moments on Fe atoms and a concomitant magnetic polarization of Au atoms, together with a strong damping of the particle SPR signal. These studies are only at their beginning, and much work will be needed to achieve proper control on the synthetic protocols and detailed comparison between theory and experiment, but they point to a promising evolution in a near future [11.277]: For example, one fascinating goal in this field is to produce photoswitchable nanomagnets that can be controlled and monitored by light [11.278].

11.4.4 Magnetic Properties

The magnetism of hybrid nanostructures is the subject of Chap. 12 in this handbook. We thus refer to this other

chapter for basic information on concepts, theory, and experimental techniques used for synthesizing and characterizing magnetic nanoalloys, and in this subsection focus on only one example to illustrate a different (surface science) approach: the use of self-assembled Co-Pt (and Fe-Pt) nanoparticle arrays as potential candidates for high-density data storage.

We start by recalling that first-row transition metals from the middle of the row possess high magnetic moments due to the presence of partly occupied d-orbitals. A quantity which is crucial for applicative purposes is the magnetic anisotropy, i.e., the preferential orientation of magnetization in a particular crystal axis direction. The magnetic anisotropy consists of two major components: crystalline anisotropy and shape anisotropy. Here we consider only magnetocrystalline anisotropy, which is of atomic origin and stems from the interaction of spin-orbit (L - S) coupling with crystal field energy. If the thermal energy is much smaller than the magnetic anisotropy energy (MAE), i.e., the energy barrier to reorient the direction of the particle magnetic moment satisfies $KV > 25\text{--}40k_{\text{B}}T$, where K is the magnetocrystalline anisotropy energy density and V is the volume of the particle, then a particle with its spin oriented in a given direction will maintain it for a long time, and could be used as a magnetic bit. The magnitude of spin-orbit coupling (which scales as a power of the atomic number) is small for first-row transition metals and large for third-row ones, actually so large for the latter that it effectively quenches magnetism in extended structures. Alloying a first-row transition metal with a third-row one is a way to produce systems which exhibit at the same time high magnetic moments and high magnetocrystalline anisotropy energy. Indeed Co-Pt and Fe-Pt bulk alloys at 50–50% composition crystallize in the $L1_0$ phase, i.e., a phase with a tetragonal crystal lattice of alternating homogeneous Pt and Co planes along a (001) axis, and are the bulk materials with the highest MAE values: around 0.8–1.0 meV per magnetic atom. Such a high MAE value entails that – in principle – Co-Pt nanoparticles of ≈ 3000 atoms could be used as magnetic bits. Note also that, being so small, they are expected to be single-domain ferromagnetic particles. Due to their potential applications in future high-density magnetic recording in multiterabit data storage and high-energy-density permanent magnets, Co-Pt and Fe-Pt nanoparticles have thus received immense research interest. In an important work [11.61] it has been proved that assemblies of high-coercivity FePt particles of ≈ 4 nm in size can in principle support stable magnetization. In order to real-

ize this possibility, however, several constraints should be satisfied. First, the particles should be in the $L1_0$ face-centered tetragonal (fct) phase and not in the disordered fcc phase or other phases exhibiting small MAE. Second, one should achieve long-range-ordered two-dimensional arrays of such nanoparticles. Third, their easy magnetization axis should be perpendicular to the plane of the substrate on which they are deposited. Perpendicular magnetization in fact allows smaller bit size and increases data storage density. Moreover, Kerr rotation of polarized light is larger when the magnetization is perpendicular to the plane compared with the in-plane magnetization. Fourth, their MAE should be at least as high as in the bulk – the higher the better.

The first requirement immediately poses some problems. As recalled in Sect. 11.4.1, in fact it has been shown both theoretically for free particles [11.156, 279] and experimentally for particles embedded in weakly interacting substrates such as amorphous carbon [11.158] that noncrystalline structures, in particular polyicosahedral (plh) ones [11.128], are favored for Co-Pt and Fe-Pt nanoalloys up to 3–4 nm diameter. The interaction with a substrate could reverse the situation and favor fct configuration. As the lattice parameter of the $L1_0$ fct phase is not too distant from that of pure Pt, and it is known that Pt clusters on MgO(100) adopt a fcc structure at very small sizes, contrary to what happens in the gas phase, one could think that the square-symmetry MgO(001) substrate should favor the $L1_0$ fct phase for Co-Pt nanoparticles. This expectation is only partly fulfilled: as recalled in the subsection on structural properties, for Co-Pt clusters smaller than 100–200 atoms, Frank–Kasper structures are favored also when deposited on MgO(100) [11.152], and interfacial adhesion actually enhances the stability of these structures, via a novel epitaxial adhesion mechanism. It is important to observe that one of the reasons for this phenomenon is that the lowest-energy structures of Co-Pt/MgO(100) particles are dominated by Co segregation at the interface with the substrate. For larger particles, the situation changes again. First, the plh configurations become progressively less and less stable with respect to fct ones due to a less efficient interfacial matching, so that they are not favorable any more for particles with more than 200 atoms. Second, for fcc-like particles, one finds a strong tendency of Pt to form a segregated layer at the topmost (100) facet from both theoretical predictions and experimental observations [11.153, 280]. For these particles, then, one-layer Co surface segregation at the interface together with

Fig. 11.44a,b Isocontours of differential electronic density $\Delta\rho = \rho(M_z) - \rho(M_y)$, obtained by subtracting the total electron density of the state in which the magnetization axis is parallel to the surface and perpendicular to the wire main axis (M_y) from the state in which the magnetization axis is perpendicular to the surface (M_z), for suspended (a) or supported (b) wires. In the larger images on the left, the view is taken along the main axis of the wire; on the right, side view of the wire is also shown. Contour value $= 0.004 \text{ e}/\text{\AA}^3$. Planes of cobalt atoms are displayed in blue; platinum atoms are displayed in dark gray. (After [11.39] with permission of ACS)

one-layer Pt surface segregation at the topmost facet translates into $L1_0$ chemical ordering, which is the first of the requirements quoted above (Fig. 11.3).

As for the second requirement, i. e., long-range 2-D order of possibly size-selected particles, we will not discuss this in detail, but we refer to the concept of surface nanopatterning in order to achieve it [11.93–95]. As the $L1_0$ chemical ordering is realized with Co planes in (100)/(100) epitaxy, one expects that the easy magnetization axis of the particles should be perpendicular to the plane of the substrate on which they are deposited, and this is indeed what is predicted by simulations exploiting 1-D modeling [11.39], thus satisfying the third requirement quoted above. Simulations however give a disappointing response in terms of the fourth requirement. Despite the fact that the particles have high magnetic moments, in fact, it is found that the mix-

ing of particle and oxide electronic wave functions at the interface dominates and results in a reduction of the MAE by a factor of at least $\approx 1/2$ [11.39]. The value of the MAE depends on which type of d-states are available at the Fermi energy. As shown in Fig. 11.44, tilting the magnetization axis of the wire from perpendicular to parallel to the (100) planes move electrons into orbitals occupying (100) planes. Furthermore, the increase of the regions where $\Delta\rho$ is large in Fig. 11.44b with respect to Fig. 11.44a indicates greater availability of d-states at the Fermi energy in the supported system, which reduces the energy cost associated with

tilting the magnetization and thus the MAE. This finding in a highly controlled and regular interface points to an even larger effect when a rougher environment is present and rationalizes the experimental difficulties in achieving supported particles with a stable and non-fluctuating magnetization direction [11.281]. Supports other than MgO(100) can be however considered in the search for systems with a stable magnetization. This example – although negative for our purposes – shows how subtle the interplay of structural and electronic effects can be in determining the magnetic properties of alloy nanoparticles.

11.5 Nanostructured Bulk Alloys

The possibilities opened by nanotechnology over the last two decades in terms of manipulating composition and structure at the atomic level are hard to overemphasize, permeating into all major science and technology domains. While much has already been achieved, much more is expected, as can be inferred by the funding strategies of the major scientific organizations around the world.

While the previous part of this chapter has addressed nanoparticle alloys, we focus in this section on bulk materials whose internal structure has been designed at a nanometer scale to achieve desirable properties, not accessible at larger scales.

Alloying has been part of metallurgical practice since historic times, but it is only recently that nanoscale structured alloys have captured the attention of the scientific and technological audience.

Many amazing properties emerge as the scale of a structure is reduced to the nanometer range. The general reader is probably familiar with the continuous progress in miniaturization of electronic devices, which allows for impressively dense packing of our electronic tools and toys, but is probably less familiar with a similar revolution taking place in other domains of nanoscience/technology, including the mechanical properties of structural materials and radiation damage for new concepts in the field of nuclear energy.

We focus here on a few aspects of nanoscale alloying, namely the search for ultrastrong materials with capability to withstand extremes in temperature, stress, radiation doses, and/or plastic deformation.

Many avenues are explored in this quest; in fact, so many that here we choose only two, namely: (i) bulk materials that incorporate nanoscale precipi-

tates of a different phase, generally oxides, and (ii) bulk nanophase materials that aim at reducing the grain size of a polycrystal to dimensions in the nanometer scale so as to incorporate a large amount of grain boundary interfaces.

11.5.1 Bulk Materials Incorporating Nanoscale Precipitates of a Different Phase

Usually the strength of a material is given by a combination of factors that are optimized by both the constituents of the material and the processing steps that produce the final microstructure.

Steels are basically iron-carbon alloys with additions of other elements such as Cr, V, Mn, Si, W, Ni, Ta, and Nb. Alloying elements in solid solution are used to produce solution hardening and also to react with C and produce fine-scale carbide precipitates that induce precipitation hardening. Also, alloying elements alter the kinetics of phase transformations, allowing easier handling of the thermal treatments that control the final hardening. Finally, some elements such as Cr enhance corrosion resistance.

Nanostructured ferritic alloys (NFA) are 12–20% Cr ferritic stainless steels that are dispersion strengthened by a very high density (up to several 10^{23} particles/m³) of ultrafine Y-Ti-O-enriched nanofeatures. Their roots trace back to the pioneering work of Fisher, who patented a mechanical alloying (MA)/hot extrusion powder processing route to produce NFAs, which were marketed in the 1980s as International Nickel Company (INCO) MA956 and MA957 [11.282]. Extensive studies in the US breeder reactor program showed that MA957

Fig. 11.45 Picture of the structure of a ODS steel showing the high density of nanometer-scale precipitates. (After [11.284] with permission of Taylor & Francis)

has high tensile and creep strengths as well as unusual resistance to radiation damage [11.283].

The oxide particles provide hard and stable dislocation pinning centers that improve the mechanical strength. They also provide sites acting as sinks for defects produced by irradiation. Figure 11.45 shows an example of the microstructure of an oxide dispersion strengthened (ODS) steel showing a very high density of nanoparticles [11.284].

These materials are currently under development at several places around the world, mainly for general high-temperature and for nuclear fission and fusion applications, in particular in the USA, Europe, and Japan. The main interest is fueled by the substantial increase in strength at high temperatures, creep resistance, and irradiation response that is obtained.

Given the significantly large composition–processing parameter space that define steels, and the fact that most of the knowledge is empirical, every laboratory/industry has its own composition and processing path, the goal being to obtain the finest particle size distribution and the highest number density.

Research in Japan led to the development of dual-phase 9Cr nanostructured transformable steels (NTS) for fast-reactor fuel cladding, as described in a recent review [11.290]. The Japanese program placed special emphasis on working–recrystallization sequences that are necessary for plate and tubing fabrication and that also produce more isotropic properties [11.284, 291–295].

In Europe, various processing and characterization studies were performed on MA957 and small experimental heats of NFAs [11.296–298]. More recently, European research programs aimed at developing

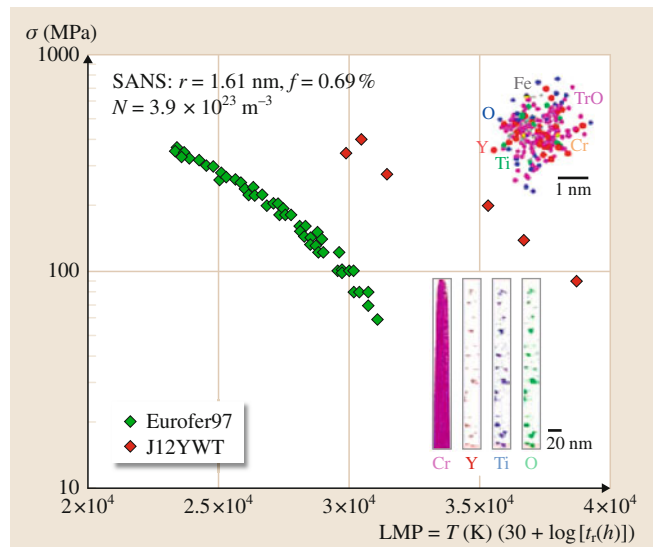

Fig. 11.46 A Larson–Miller plot (LMP) comparing the creep strength of nanostructured ferritic alloys J12YWT [11.285] with that of normalized and tempered martensitic steel Eurofer97 [11.286]. The insets show atom probe tomography maps of the nanofeatures (NF) in J12YWT [11.287]. SANS data on the NF size (r), number density (N), and volume fraction (f) are shown (top left). (After [11.288, 289])

the martensitic ODS Eurofer97 for fusion applications [11.299, 300].

In the USA, Klueh et al. [11.301, 302] have worked on NFA for possible use up to 700 °C, a substantial increase in maximum operation temperature of steels containing 9% Cr, such as T91, which is of the order of 590 °C. This is illustrated in Fig. 11.46, which shows a creep rupture time (t_r) Larson–Miller plot for a Japanese NFA, J12YWT [11.285], compared with a 9Cr TMS Eurofer97 [11.286]. (Note: the Larson–Miller plot shows the maximum stress a material can sustain at a given temperature before rupture at a given time.) The insets show an atom probe tomography (APT) map and Y-Ti-O cluster image for the NFs in J12YWT [11.287], along with the average radius (r), number density (N), and volume fraction (f), measured by small-angle neutron scattering (SANS) [11.288, 289, 303].

These ultrafine-scale features distinguish NFAs from conventional dispersion strengthened ODS alloys, which generally contain refined, but larger, equilibrium oxide phases.

Regarding strength at high temperature, the ODS alloys developed under the Japanese High Burnup

Fig. 11.47 Strength of two ODS steels developed by Kimura et al., compared with traditional ferritic steels. (After [11.284] with permission of Taylor & Francis)

Fuel Cladding Materials R&D program by Kimura et al. [11.284] show a significant increase in tensile stress compared with conventional ferritic steels (Fig. 11.47). These alloys are being irradiated in Japan and Russia to reach high displacements per atom (dpa) levels (in the range of ≈ 200 dpa), and the results will be available in a few more years.

Swelling Resistance

As already mentioned, besides the increase in strength/creep behavior at high temperature, one of the most interesting properties of NFAs is their ability to resist radiation damage. In a nutshell, radiation damage comprises a series of phenomena produced when energetic particles hit a solid. Among them the displacements of atoms, creating interstitials and vacancies, and the transmutation of the original species into new ones via nuclear reactions are the most important. For future nuclear fusion application, the requirements on materials are extreme due to the large damage produced by energetic 14 MeV neutrons in terms of both displacements (measured in displacements per atom, or dpa) and He generation via fusion of D and T and decay of heavy elements, measured in He/dpa. Vacancies and He atoms have a tendency to coalesce into voids and bubbles that induce swelling and promote intergranular or creep fracture via a fine dispersion of bubbles at grain boundaries.

The lifetime under creep conditions is determined by the kinetics of bubble growth. Nanofeatured alloys show excellent capacity to prevent He-induced embrittlement via the ability to capture He at fine bubbles at

the interface between the oxide particles and the matrix. Intensive work is being pursued at present, trying to understand quantitatively this behavior in order to define the best type of interfaces for this purpose, also in materials other than steels [11.304].

The fabrication of ODS or NFA alloys at industrial scale remains a challenge; at present no commercial ODS steels are produced. At the laboratory level, an example of a synthesis route is as follows [11.305]: Starting from 70 μm -diameter, argon-atomized, prealloyed metal powders and 20 nm Y_2O_3 powder, the process involved milling in a high-energy attritor mill in an argon atmosphere. After the mechanical alloying step, the flakes are degassed and consolidated into a bar by hot extrusion at 1150 $^\circ\text{C}$. Further processing by hot and cold rolling interspersed with annealing treatments is used to convert the extruded bar into sheet with final thickness of 2 mm. A schematic picture of the process is shown in Fig. 11.48.

One of the most detailed studies of the morphology and stoichiometry of these nanoparticles is that of Hsiung and collaborators, working on one Japanese ODS steel named K3, with a composition that includes Al: 16Cr-4Al-2W-0.3Ti-0.3 Y_2O_3 [11.306–308]. Using high-resolution TEM and software to simulate diffraction patterns, they were able to resolve the chemical composition of these particles and to propose a possible path for their formation from the original powder to the final precipitate. They found that the oxide nanoparticles (Fig. 11.49) are mainly $\text{Y}_4\text{Al}_2\text{O}_9$ (YAM), a complex oxide with monoclinic structure, mean particle size of 6 nm, and particle density of $1.33 \times 10^{22} \text{ m}^{-3}$.

By comparing the $\text{Y}_4\text{Al}_2\text{O}_9$ nanoparticles formed in the ODS steel with the starting Y_2O_3 particles (space group $Ia\bar{3}$, a cubic structure, with size between 15–30 nm) used to fabricate the ODS steel, these authors suggest that the formation of oxide nanoparticles in ODS steels does not take place solely through a fragmentation mechanism, but requires the decomposition of Y_2O_3 through $\text{Y}_2\text{O}_3 \rightarrow 2[\text{Y}] + 3[\text{O}]$ and the following internal oxidation reactions: $2[\text{Al}] + 3[\text{O}] \rightarrow \text{Al}_2\text{O}_3$ and $2\text{Y}_2\text{O}_3 + \text{Al}_2\text{O}_3 \rightarrow \text{Y}_4\text{Al}_2\text{O}_9$ during MA and consolidation, in which the internal oxidation reactions are governed by the oxygen affinity of alloying elements: That is, the formation of Y-Al complex oxides becomes predominant when both Al and Ti are present in ODS steels.

The small nanoparticles (< 10 nm) show facets and ledges at the oxide–matrix interfaces and tend to be coherent or semicoherent with the matrix. A structure of

crystalline oxide core in association with amorphous shell was observed in both large and small nanoparticles in as-fabricated K3 ODS steel. The core-shell structure vanishes after prolonged annealing at 900 °C for 168 h, suggesting that the core-shell structure is far from chemical equilibrium. A three-stage formation mechanism of ODS nanoparticles including fragmentation, amorphization, and crystallization is accordingly proposed to rationalize the observations.

Other recent studies also describe the evolution of these particles for different alloy compositions. The MA957 ODS alloy was studied by *Kaoumi* [11.310], with a composition that includes 1 Ti and 0.3 Mo, besides 0.25 Y₂O₃ (wt%). Titanium and molybdenum are added in small quantities to improve the ductility and the oxidation resistance of the material; they give solid-solution strengthening in iron. Also, they are believed to trap the carbon and nitrogen present in the matrix, thus preventing the formation of chromium carbides and nitrides, which are a cause for grain boundary embrittlement.

The ambient- and elevated-temperature strength of an alloy can be improved by plastic deformation (hot or cold working). However, in conventional alloys which do not contain a fine dispersion of a second phase, the strengthening provided by the cold and hot working quickly anneals out when exposed to high temperatures, due to migration of dislocations and recrystallization of the new grains. Mota explains that the presence of a uniformly distributed dispersoid can prevent recrystallization by blocking the dislocation migration.

The advantage of using yttria instead of other oxides, carbides, or nitrides is its relative stability at high temperatures. Other refractory oxides, carbides, and nitrides would be suitable as dispersoid materials provided that they have such high temperature stability; such suitable dispersoids are thoria, ceria, and rare-earth oxides, carbides or nitrides of zirconium, titanium, and hafnium. The less desirable materials are alumina, titania, and chromium carbides since it is expected that their size should increase at high temperatures, making them less efficient at retarding the recrystallization process.

The worldwide interest in this type of alloys is so large that moving the frontier forward, well above 200 dpa, is to be expected soon as basic science based on computational materials modeling in combination with careful experimental validation may accelerate the optimization of alloys in ways never foreseen before.

Finally, *Odette* and *Hoelzer* [11.311] believe that, while there are still unresolved challenges facing the successful development of nanostructured ferritic al-

Fig. 11.49a,b HR-TEM images of a large Y₄Al₂O₉ (YAM) nanoparticle at two different defocus conditions (a) -75 nm, (b) -50 nm. (After [11.306] with permission of APS)

loys, these challenges also represent opportunities for materials science to make critical contributions, akin to the superalloy single crystals that revolutionized the jet engine and gas turbine technologies.

In summary, we have presented here a small part of a huge international effort to develop ferritic alloys capable of preserving their strength at high temperatures, resisting creep and radiation damage, and managing He, an undesirable byproduct of radiation damage in fast/fusion reactor technology.

11.5.2 Bulk Nanophase Materials

We focus now on a field that has been growing quickly for the last two decades, namely the development of

nanophase materials, i. e., bulk materials with grain size below 100 nm. These materials have generated interest in terms of both basic science and technological applications due to their unusual mechanical [11.312–319], electrical [11.320–322], magnetic [11.323–328], and corrosion [11.329–331] properties.

From the perspective of mechanical response, nanophase materials present amazing properties since, as the grain size decreases, a well-known hardening law – the Hall–Petch relation [11.332] – predicting that the yield strength increases as $1/d^{1/2}$ (grain size strengthening) – anticipates an unprecedented increase in hardness [11.333]. *Chokshi et al.* [11.334] were among the first to report that pure nanocrystalline Pd materials become extremely hard with decreasing grain size. With progress in synthesis techniques leading to the nanometer grain size regime, exceedingly high strength has been obtained.

However, below a grain size limit of around 10–20 nm, the Hall–Petch relation ceases to be valid and a new world of nanomechanics appears, where plasticity generated at grain boundaries (GBs) becomes relevant [11.335–338]. Below 10–20 nm materials begin to soften, giving rise to a so-called inverse Hall–Petch (HP) regime. This general behavior occurs in a number of pure metals and intermetallic compounds [11.339, 340]. Since these early experiments till today, a great deal of effort has been focused on elucidating the physical mechanisms that control plasticity in nanocrystalline materials, both experimentally and through molecular dynamics (MD) computer simulations [11.312, 337], that has not yet succeeded in providing a conclusive picture.

Recent experimental investigations have suggested that the earlier measurements showing an inverse HP behavior may not represent an intrinsic nanocrystalline behavior but rather are a consequence of defects in the samples, such as porosity and grain boundary (GB) contamination [11.314, 338, 341, 342].

The molecular dynamics (MD) studies, on the other hand, reproduce an inverse HP behavior [11.336, 343], most notably the work of *Schiotz et al.* [11.318], which extended earlier observations [11.336] to grain sizes of 5–50 nm.

Nearly all such simulations conclude that the cause of the inverse HP behavior arises from a crossover in the mechanism of deformation from dislocation glide to GB sliding. However, none of these MD computer simulation studies had provided a quantitative account of these two mechanisms or how one mechanism switches to the other, until a recent work by *Lebensohn et al.* at the con-

tinuum model level [11.344] and *Vo et al.* [11.345] using MD. These works aimed at quantifying the contribution to total plasticity coming from intragrain dislocation activity and GB-mediated mechanisms. What was found is that, for all but the highest strain rates, plasticity comes from equal contributions from GB and from intragrain dislocation activity, suggesting that the two mechanisms are closely related.

Further studies by *Vo* on the limits of hardness at the nanoscale [11.333] bear a remarkable similarity to a recent experimental report by *Trelewicz and Schuh* [11.346], who succeeded in preparing a set of Ni–W alloy samples with grain size between 3 and 150 nm using pulsed electrodeposition. They observed that, as the grain size decreases, plasticity shifts from crystal-like behavior (Hall–Petch) to amorphous or glassy-like behavior, where hardness is independent of grain size.

In summary, what *Vo's* work shows is that, by relaxing the grain boundaries by a brief high-temperature annealing treatment, the strength of nanocrystalline materials as simulated by MD in a computer can be greatly modified. In particular, plasticity in unrelaxed samples shows a transition from normal Hall–Petch behavior for grain sizes above 12 nm to inverse Hall–Petch; in partially relaxed samples, a regime below 12 nm is observed where the strength becomes independent of grain size, and in samples undergoing grain growth during relaxation, the Hall–Petch behavior extends to significantly smaller grain sizes. This analysis linking the relationship between GB sliding and GB relaxation offers a key to resolve the long-standing controversy concerning the inverse Hall–Petch relation, as it illustrates that grain size alone is not sufficient to characterize hardness in nanoscale systems but that a measure of GB relaxation is required as well.

Vo's observations bring about a connection to alloying effects. Nanocrystalline materials are generally unstable due to the large volume fraction of interface regions, representing high-energy far-from-equilibrium structures. Consequently their synthesis has proven challenging [11.347–349], and in many cases, they cannot be produced in bulk form. For potential applications, the problem of stability has to be addressed.

Pure metals such as Cu, Pd, Sn, Pb, Al, and Mg in nanocrystalline phases exhibit grain growth even at room temperature [11.350–352].

The standard procedure in metallurgy to lock in a desired microstructure is to explore alloying routes, which in this particular problem of nanophase materials led to significant advances in nanostructure stability at elevated temperature compared with their pure metal

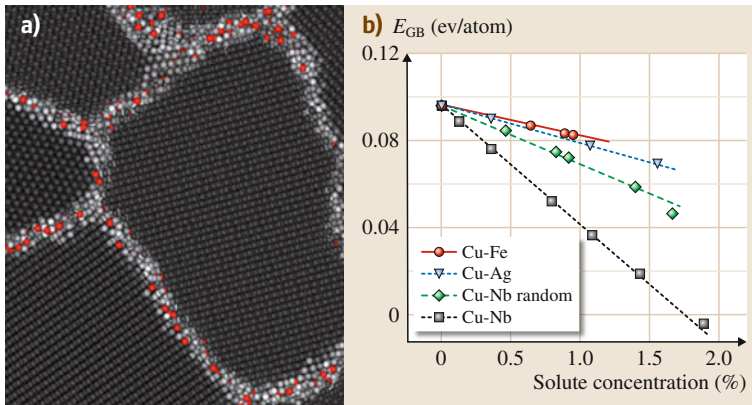

Fig. 11.50 (a) Atomic configuration of an MC/MD Nb-doped Cu nanocrystalline (nc) sample showing that the solute is fully segregated in GB. (b) Specific GB energy as a function of solute concentration in nc Cu. (After [11.365] with permission of Elsevier)

counterparts [11.353–358] and has enabled synthesis of materials with the finest possible length scales [11.359–364].

Thermal stability of a microstructure has traditionally been linked to kinetic phenomena [11.366]: by alloying the grain boundary, mobility is decreased. However, it has been suggested that the improved stability at the nanoscale may also derive from a thermodynamic reduction in grain boundary energy [11.365, 367–369]. With reduced grain boundary energy, the driving force for grain growth decreases, and in the extreme case of zero boundary energy, it becomes null. In this scenario, a high volume fraction of intergranular regions would represent no energy penalty to the system and nanocrystalline structures could therefore exist in equilibrium.

The idea of thermodynamically stabilizing nanocrystalline (nc) alloys by eliminating the energetic penalty of grain boundaries was first introduced by *Weissmüller* [11.370], who presented a simple model to illustrate that nanocrystalline structures might exist in a stable state. The basis for grain boundary energy reduction relies on a heterogeneous distribution of solutes, where alloying atoms preferentially occupy grain boundary sites (Fig. 11.50).

Schuh and collaborators have worked extensively on the Ni-W system, which exhibits significant solubility (≈ 12 at.% at room temperature) and consequently a weak tendency for grain boundary segregation [11.364]. Despite this weak tendency to segregate, they have shown that W can be used to control the grain size in nanocrystalline Ni as shown in Fig. 11.51, and that the materials also show negligible grain growth even above 500°C [11.353, 364, 368, 371] despite not reaching the zero GB energy.

Analytical models for this phenomenon have been proposed [11.354, 367, 368, 372, 373]. An interest-

ing conclusion from these works is that, as solutes prefer GB sites, an increase in global composition promotes an increase in GB area and thus a decrease in grain size, implying that nanocrystalline grain size might be tailored via the composition of the alloy [11.364].

Recently, computational work by *Vo* et al. [11.365] probed these ideas in nanocrystalline Cu alloyed with Fe, Ag, and Nb. Figure 11.52 shows stress–strain curves for several compositions of Nb-doped nc Cu and the yield stress versus composition for several alloying elements.

These authors summarize their results in terms of the lattice mismatch between solute and matrix

Fig. 11.51 Experimental grain size–composition relationship in electrodeposited Ni-W and Ni-P. Increasing the global solute content leads to a decrease in nanocrystalline grain size. (After [11.364] with permission of Elsevier)

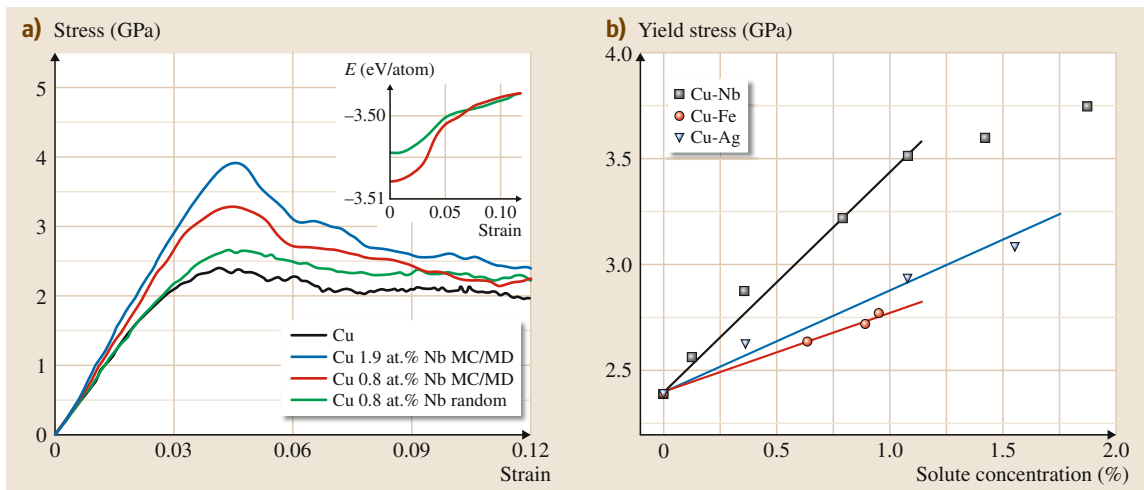

Fig. 11.52 (a) Stress–strain curve of pure and Nb-doped nc Cu at constant strain rate of $1 \times 10^9 \text{ s}^{-1}$. Potential energy as a function of strain of Cu 0.8 at. % Nb MC/MD and random-GB samples are shown in the inset. (b) Yield stress of MC/MD nc Cu alloys as a function of solute concentration at constant strain rate of $1 \times 10^9 \text{ s}^{-1}$. (After [11.365] with permission of Elsevier)

(Fig. 11.53). In terms of this variable, they find a linear relationship for the GB energy and the yield strength, with Nb being the best alloying element in Cu to increase both strength and thermal stability.

Solute addition to GBs in nanophase materials affects not only the GB energy but also its gliding and bonding characteristics [11.358]. Figure 11.54 shows how alloying nc Cu with 3% Fe changes the spalling

Fig. 11.54a–c Results of shock-wave simulation in pure and nanoalloyed samples: (a) as prepared, (b) pure Cu sample, and (c) sample containing 3% Fe. The arrows show the direction of the incoming laser shot. (After [11.358] with permission of Trans Tech Publications)

behavior under shock loading, reflecting changes in GB cohesion.

In summary, we have reviewed a small number of papers in the abundant literature, addressing the alloying route to improve the stability and mechanical properties of nanophase materials. This field is still at a development stage, but its potential cannot be overstated, as it promises to deliver bulk ultra high-strength materials for a diversity of applications.

11.6 Applications

In this section we give a few examples of the applicative use of nanostructured alloys. Its aim is mostly to provide a very brief illustration of the capabilities of these materials, while we refer to the chapters on fuel cells and energy storage (Chap. 28), nanomedicine (Chap. 30), magnetic nanostructures (Chap. 12), and plasmonics (Chap. 9) in this handbook for more detailed and thorough discussion.

First of all, alloy nanoparticles are very relevant in heterogeneous catalysis. We have mentioned above as one of the first examples the much higher selectivity of Cu-Ru particles with respect to pure Ru ones in orienting dehydrogenation of cyclohexane into benzene rather than its hydrogenolysis into methane [11.22]. We have also mentioned that the Ni₃Fe system was proposed and indeed found to be an efficient methanation catalyst [11.178], and we show in Fig. 11.55 the data on which the theoretical prediction was grounded together with its experimental validation.

In this context, alloys seem very promising in the very important field of heterogeneous catalysis for carbon management [11.374], i.e., to achieve a carbon-neutral cycle in the world economy.

Another fundamental field is the practical application of the optical and magnetic properties of nanoalloys for chemical assays and nanoscale biological research. It is important to underline that in 2011 an entire issue of the *Accounts of Chemical Research* [11.375] was dedicated to theranostics, a term derived from therapy + (diag)nostics to link the fields of diagnostics and therapeutics in medicine. We have mentioned in the previous section how plasmonic nanostructures can enhance or enable the detection of molecular processes [11.376]. In this context, nanoalloys are useful for example in the synthesis and fabrication of new nanostructures with nanoparticle-surface interactions or chains of plasmonic nanostructures for the propagation of plasmons along confined geometries. Gold nanocages (nanostructures characterized by a hollow core and an ultrathin porous shell) exhibit tunable plasmonic peaks in the near-infrared region, being prepared by galvanic replacement from Ag nanocubes [11.71], but incomplete replacement could lead to hybrid structures with potentially improved features.

Metal nanoparticles are also already utilized and many more applications are prospected in therapeutic and diagnostic applications, after proper functionalization to improve or achieve biocompatibility [11.377].

A biomedical application which is currently under development but that holds great promise for the future and should not present great difficulties for full exploitation is the use of the attraction between magnetic nanoalloys and external fields to separate biomolecules such as proteins, bacteria, and cells. As an example, biofunctionalized Fe-Pt nanoparticles were shown to be able to capture and separate Gram-positive bacteria, as illustrated in Fig. 11.56 [11.378].

Another biomedical application currently under development is the use of magnetic nanoalloys as imaging probes for biological events via magnetic resonance imaging (MRI). The magnetic field generated by the nanoparticle in fact perturbs magnetic relaxation processes and thus alters the contrast in MRI response [11.379], as shown in Fig. 11.57. By using such MRI contrast effects of magnetic nanoparticles as probes, it will be possible to observe molecular events in biological systems.

In terms of magnetic properties, Fe-Co nanoparticles have the advantage of high magnetizations, but present the issue of being very reactive and undergoing fast oxidation in biological solutions. Once coated

Fig. 11.55 Pareto plot of the activity measure $\Delta E_{\text{diss}}(M) = |E_{\text{diss}}(M) - E_{\text{diss}}(\text{optimal})|$ and the cost for 117 elemental metals and bimetallic alloys of the form A_xB_{1-x} ($x = 0, 0.25, 0.50, 1$). Each blue point corresponds to a particular alloy. The elemental metals are shown (black), and the Pareto-optimal set is also indicated (red). The cost of the bimetallic alloys has been approximated by the current commodity price of the constituent elemental metals. (After [11.178] with permission of Elsevier)

(After [11.379] with permission of RSC)

with a layer of Fe_3O_4 or other protective agents, they can provide better contrast for MRI and more effective heating for magnetic fluid hyperthermia. Fe-Pt nanoparticles are interesting for their chemical stability and have shown great potential as contrast agents for both MRI and x-ray computed tomography, and as robust

probes for controlled heating in magnetic fluid hyperthermia [11.380]. Finally, the combination of optical and magnetic response is very promising: For example, Au-Fe nanoparticles could be useful in simultaneous diagnostic imaging and photothermal ablation therapy of cancer (multimodal imaging and therapeutics) [11.381].

11.7 Concluding Remarks

In this chapter, which is far from being exhaustive, especially in terms of literature citation (and we apologize to the authors of important contributions not cited for reasons of space or presentation), we have presented a brief overview of nanostructured alloy materials as both isolated particles with nanoscale diameter (nanoparticles) and bulk materials with nanoscale structure. We have discussed the methods for preparing and characterizing these systems from both the experimental and theoretical modeling points of view, and reviewed some basic knowledge on their structural, catalytic, mechanical, optical, and magnetic properties. Attention has been focused on concepts and methods which can help rationalize the available information and provide a general framework for future investigations. Even from

this brief overview, the importance of nanostructured alloys in the field of nanoscience and nanotechnology should appear clear. By taking advantage of the degrees of freedom associated with composition and chemical ordering it is possible to expand the scope of physical phenomena exhibited by metal nanosystems and modulate or even dramatically change their corresponding properties. Catalytic activity, mechanical strength, plasmonic and nonlinear optical, as well as magnetic response, or the combination of these features, can all be tuned to meet the requirements of applications. This has already been achieved in some cases, such as in heterogeneous catalysis and nanomagnetism, but to an extent which is only a fraction of the actual potential. In order to better exploit these

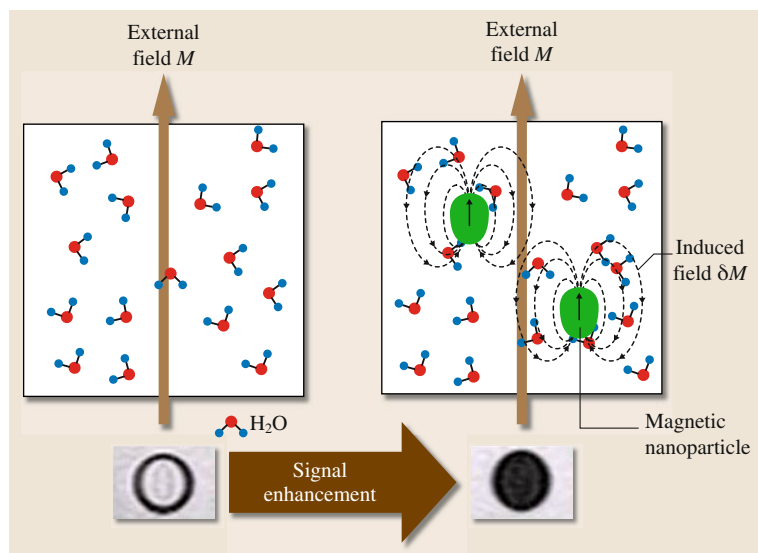

Fig. 11.57 Magnetic contrast effect of magnetic nanoparticles in water. Induced magnetic field by magnetic nanoparticles perturbs the magnetic relaxation processes of the protons in water molecules, which results in shortening of T_2 of the proton with dark MR contrast. (After 11.379 with permission of RSC)

opportunities, precise control of synthetic protocols, improved experimental and theoretical characterization techniques, and fundamental understanding still need to be further advanced, and this represents the major challenge of both basic and applied research in the years to

come. Our hope is that the present overview will contribute to promote interdisciplinary research (especially as concerns the interaction between theory and experiment) and advance the general field of nanostructured alloys.

12. Magnetic Nanostructures: Synthesis, Properties, and Applications

Shashwat Shukla, Pratap Kumar Deheri, Raju V. Ramanujan

Advances in magnetic nanostructures are rapid in the field of science and technology due to the unique magnetic properties observed at the nanoscale such as superparamagnetism, enhanced magnetic moment, high saturation field, shape anisotropy, etc. The common morphologies of magnetic nanostructures are dots, nanoparticles, nanocrystals, nanowires, nanotubes, and thin films. With the emergence of new synthesis and fabrication techniques, magnetic nanomaterials with diverse shapes and sizes have been fabricated and their structure–property relationships established. Characterization techniques such as magnetic force microscopy (MFM), Lorentz microscopy, magnetometry based on superconducting quantum interference device (SQUID), and small-angle neutron scattering (SANS) have been utilized to study magnetism in nanostructures.

In this chapter, the magnetism of atoms is discussed and the effect of nanostructuring on magnetic properties is reviewed. Characteristic magnetic length scales are presented. When the size of magnetic materials, in at least one dimension, becomes comparable to characteristic magnetic length scales, size-specific magnetic properties such as superparamagnetism, remanence enhancement, random anisotropy, and giant magnetoresistance (GMR) effects are observed. The change in magnetic moment and anisotropy with dimensionality is discussed; e.g., broken symmetry at surfaces and interfaces may increase magnetic moment compared with the bulk counterpart. In nanostructured materials, shape and surface anisotropy is induced and thickness dependence of anisotropy is observed in thin films.

Magnetization reversal mechanisms and the use of micromagnetic modeling in establishing microstructure–property relationships are discussed.

sed. Magnetic nanostructures such as particles, nanowires, nanorings, thin films, and molecular nanomagnets are reviewed. Current trends in synthesis by physical (melt spinning, ball milling, sputtering, and molecular beam epitaxy (MBE)) and chemical (reduction, self-assembly, and electrodeposition) processes are outlined. The use of atomic force microscopy, Mössbauer spectroscopy, electron holography, scanning electron microscopy, and transmission electron microscopy is discussed. The magnetic properties of hard and soft nanostructured magnets are reviewed. Exchange-coupled nanocomposites and the GMR effect are also discussed. Applications of magnetic nanostructures in data storage and biomedical applications are summarized.

12.1 Background

Magnetic nanostructures are attracting considerable interest due to their unique properties and potential applications in storage, sensing, spintronic, and optoelectronic technologies. The magnetic properties of nanostructures are governed by several factors such as composition, shape, size, surface morphology, anisotropy, layer thickness, and molecular interactions. There is a dramatic change in magnetic properties when the size reduces to a critical magnetic length scale, such as the exchange length or domain wall width; e.g., magnetization is induced in noble metals [12.1], electron interference patterns are observed [12.2], oscillatory exchange interactions between two magnetic layers separated by a nonmagnetic layer are observed [12.3], and magnetoresistivity is enhanced (GMR) [12.4].

The main thrust behind the research in nanomagnetism is the production of novel magnetic nanostructures and understanding of structure–magnetic properties relationships. Technologically, this is challenging and requires the combined effort of chemists, physicists, and materials scientists. Prior development in nanostructured materials, their magnetic properties, and theoretical discussion have been presented in the literature [12.5–8]. Magnetic nanostructures can be fabricated or synthesized into nanoclusters, nanoparticles, nanoarrays, nanowires, self-assemblies, multilayers, and thin films. Magnetic nanostructures of both hard (Nd-Fe-B, FePt, and SmCo) and soft (Fe, Co, Ni, FeCo, Finemet, Nanoperm, and Hitperm) magnetic materials have been studied [12.9]. The wide range of chemical compositions as well as wide variety of nanostructures requires a variety of processing techniques, each technique being restricted to a relatively narrow class of magnetic materials; For example, nanostructured magnetic powders are produced by ball milling, anisotropic/isotropic magnetic ribbons are prepared by melt spinning, nanostructured thin films of both hard and soft magnetic materials are produced by sputtering, molecular beam epitaxy, and electrodeposition, magnetic nanowires are produced by electrodeposition in porous templates, and nanolithography is a versatile technique to fabricate magnetic dots, nanoparticle arrays, nanowires, and nanorings.

Nanostructured materials have large surface area to volume ratios, which can result in inhomogeneous magnetic properties. Due to the quenching of orbital moments in the bulk, there is no orbital contribution to total magnetic moment; hence, magnetic moment in the bulk is generally lower than that

at the surface. Surface anisotropy also differs from bulk anisotropy, and exchange interactions can vary within the nanostructure. Several methods are used for characterization of structural and magnetic properties of nanostructured magnetic materials [12.10]. X-ray magnetic circular dichroism provides information about the local magnetic environment, small-angle neutron scattering (SANS) yields information about the magnetic environment around atoms, and spin-polarized scanning tunneling microscopy (SP-STM) also yields data on the local magnetism of atoms at surfaces or interfaces. Magnetic measurements are performed by the same techniques used for bulk magnetic materials, e.g., vibrating sample magnetometry (VSM), SQUID magnetometry, and magneto-optical Kerr effect (MOKE). Magnetic force microscopy (MFM) is used for study of magnetic domains and domain wall motion. Structural characterization is performed by techniques such as scanning electron microscopy (SEM) and transmission electron microscopy (TEM).

Understanding nanostructuring-induced phenomena in magnetic materials such as spin-polarized tunneling and GMR effects requires theoretical study of atomic-scale magnetism, in addition to experimental investigations. Theoretical studies, primarily based on density functional theory (DFT), have been conducted to understand the electronic structure, and methods have been developed to relate *ab initio* electronic structure calculations with large-scale molecular dynamics simulations to elucidate the magnetic behavior of nanostructured materials [12.11–13].

Magnetic nanostructures have found a wide range of applications in information storage [12.14], magnetic resonance imaging (MRI) [12.15], drug delivery [12.16–18], magnetic hyperthermia [12.19, 20], cell separation [12.21, 22], gene delivery [12.23], and magnetic refrigeration [12.24, 25]. Hard magnetic nanostructures are used for bonded magnet preparation, recording media, and microelectromechanical system (MEMS) applications. Self-assembled FePt nanoparticle arrays are potential candidates for high-density data storage. Soft magnetic nanostructures are used in common-mode electrical chokes, high-frequency transformers, magnetic sensors, magnetic shielding sheets, and for flux guidance in permanent magnets. Nanostructuring is used to reduce magnetic losses by controlling anisotropy and eddy current losses. Magnetic nanoparticle-based magnetic relaxation switch

(MRSw) biosensors have been used for nucleic acid, protein, enzyme, and virus sensing [12.21]. When magnetic nanoparticles interact with molecular targets, they switch from dispersed state to clustered

(or the reverse); this changes the magnetic resonance of the solvent. This change of magnetic relaxation can be detected to characterize the attached molecular targets.

12.2 Atomic Origin of Magnetism

Magnetism is a force of attraction or repulsion. The magnetic properties of matter are determined by the electronic configuration. The rotation of a free electron with negative charge around its own axis produces a magnetic moment parallel to the axis. In addition, moment due to revolution around the nucleus is perpendicular to the orbit. The magnetic moment associated with the electron is calculated from the angular momentum.

According to the Bohr model, the orbital angular momentum of the electron is equal to an integral multiple of $h/2\pi$ as

$$mvr = \frac{nh}{2\pi}, \quad (12.1)$$

where m is the electron rest mass, v is the velocity of an orbiting electron, r is the radius of the orbit, and h is Planck's constant. The magnetic moment μ due to this revolution of the electron around the nucleus can be calculated from the current and area of the loop as

$$\mu = (\text{area of loop}) \times (\text{current in [emu]}). \quad (12.2)$$

If e is the charge of an electron and c is the velocity of light, the current associated with an electron is $ev/(2\pi r)$ (SI units), so

$$\mu = \pi r^2 \times \frac{ev}{2\pi rc} = \frac{evr}{2c}. \quad (12.3)$$

Combining (12.1) and (12.3) yields

$$\mu = \frac{neh}{4\pi m} [\text{SI units}]. \quad (12.4)$$

If $n = 1$, i.e., for the first Bohr orbit, the magnetic moment of an electron is $9.27 \times 10^{-24} \text{ A m}^2$ (SI units). The moment due to spin, termed the Bohr magneton μ_B , is equal to the orbital moment of an electron for the first Bohr orbit, being used in magnetic moment calculations.

12.2.1 Quantum Mechanics of Ferromagnetism

According to Heisenberg's uncertainty principle, the position and momentum of an electron cannot be

simultaneously calculated with precision. Quantum mechanics considers discrete space quantization of orbital and spin momenta through L - S coupling, being characterized by quantum numbers L , S , and J . Orbit-orbit coupling of an atom results in orbital angular momentum L , spin-spin coupling results in spin moment S , and orbital and spin moment coupling gives the total angular momentum J . These magnetic moments are expressed as

$$\mu_L = \sqrt{L(L+1)}\mu_B, \quad (12.5)$$

$$\mu_S = \sqrt{S(S+1)}\mu_B, \quad (12.6)$$

$$\mu_J = \sqrt{J(J+1)}\mu_B. \quad (12.7)$$

The net magnetic moment of an atom can be expressed in terms of μ_J and g (spectroscopic splitting factor) as

$$\mu_{\text{eff}} = g\sqrt{J(J+1)}\mu_B, \quad (12.8)$$

where μ_B is the Bohr magneton, expressed as $eh/(4\pi m)$. The angular momentum J can be used to explain magnetic phenomena such as magnetocrystalline anisotropy, magnetostriction, the Kerr effect, and anisotropic magnetoresistance.

The energy levels of the angular momentum J are discrete in an isolated atom. However, when an external magnetic field is applied, the energy levels split into different energy states to a total number of $(2J+1)$ levels; this phenomenon is known as Zeeman splitting. The possible values of the moment for different levels are given by

$$\mu_J = gM_J\mu_B, \quad (12.9)$$

where $-J \leq M_J \leq +J$. For the simple case of $J = \frac{1}{2}$, M_J takes the values $\pm\frac{1}{2}$. The lower energy level corresponds to $J = -\frac{1}{2}$ where the magnetic moment is parallel to the applied field, while the upper value corresponds to moment antiparallel to the applied field. The Zeeman energy in the magnetic field is expressed

Fig. 12.1 Reduced magnetization versus reduced temperature plot for nickel (after [12.26])

as

$$E = -\mu_J \cdot \mu_0 H = gJ\mu_B \cdot \mu_0 H = \pm \frac{1}{2} \mu_0 g\mu_B H. \quad (12.10)$$

The energy difference between these two levels is

$$\Delta E \mu_0 g\mu_B H. \quad (12.11)$$

The magnetization M depends on the ratio of atoms (N_2/N_1) in these two energy levels and can be expressed by the Boltzmann distribution law as

$$\begin{aligned} M &= g\mu_B(N_1 - N_2), \\ \frac{N_2}{N_1} &= e^{-\Delta E/(k_B T)}, \\ N &= N_1 + N_2. \end{aligned}$$

Using these expressions, the magnetization M can be expressed as

$$\begin{aligned} M &= Ng\mu_B \tanh\left(\frac{\Delta E}{k_B T}\right) \\ &= Ng\mu_B \tanh\left(\frac{g\mu_B \mu_0 H}{k_B T}\right). \end{aligned} \quad (12.12)$$

In the weak field approximation,

$$\tanh\left(\frac{g\mu_B \mu_0 H}{k_B T}\right) = \left(\frac{g\mu_B \mu_0 H}{k_B T}\right),$$

which leads to

$$M = Ng\mu_B \times \frac{g\mu_B \mu_0 H}{k_B T}. \quad (12.13)$$

The magnetic susceptibility χ can be expressed as

$$\chi = \frac{M}{H} = N\mu_0 \times \frac{(g\mu_B)^2}{k_B T}, \quad (12.14)$$

which leads to the Curie law of paramagnetism as

$$\chi = \frac{C}{T}, \quad \text{where } C = \frac{N\mu_0(g\mu_B)^2}{k_B}. \quad (12.15)$$

The quantum theory of ferromagnetism is derived from the quantum theory of paramagnetism by introducing exchange interactions between electrons on neighboring atoms as

$$E = -\mu_J \cdot \mu_0(H + \alpha M). \quad (12.16)$$

Now, if we consider the case of atoms with one electron for which the angular momentum J is $\pm \frac{1}{2}$, the magnetization M can be expressed as

$$M = NgJ\mu_B \times \tanh\left(\frac{gJ\mu_B \mu_0(H + \alpha M)}{k_B T}\right). \quad (12.17)$$

The solution of (12.17) is shown in Fig. 12.1 [12.26, 27]. For a multielectron atom, J takes values of $-J$ to $+J$ through 0 for a total of $(2J + 1)$ states. The magnetization of a multielectron atom is given by an expression using the Brillouin function B_J ,

$$\begin{aligned} B_J &= \frac{2J+1}{2J} \coth\left(\frac{2J+1}{2J}x\right) - \frac{1}{2J} \coth\left(\frac{x}{2J}\right), \\ \text{where } x &= \frac{gJ\mu_B H}{k_B T}, \\ M &= NgJ\mu_B \times B_J\left(\frac{gJ\mu_B \mu_0(H + \alpha M)}{k_B T}\right). \end{aligned} \quad (12.18)$$

12.2.2 Atomic-Scale Magnetism and Exchange Effect

Intrinsic magnetic properties, such as magnetic moment and anisotropy, are of atomic origin and involve quantum phenomena such as spin-orbit coupling, crystal field interactions, and exchange phenomena. In transition metals (Fe, Co, and Ni), magnetic moment arises from partially filled 3d electrons, whereas in rare earths magnetic moment originates from the incomplete 4f

Fig. 12.2 (a) Ferromagnetic order, (b) ferrimagnetic order, (c) antiferromagnetic order, and (d) ferromagnet above T_C

shell. Magnetic moments of atoms are calculated in terms of spin and orbital magnetic moment.

In transition metals, the strength of the spin–orbital coupling ($\approx 10^2 \text{ cm}^{-1}$) is much smaller than the crystal field energy ($\approx 10^4 \text{ cm}^{-1}$), hence the orbital moment is quenched. Due to quenching of the orbital moment, typically $\approx 0.1\mu_B$, only the spin moment contributes to magnetic moment. The moment of transition metals is determined by μ_B and the total number of unpaired electrons. In contrast, in rare earths, the strength of spin–orbital coupling ($\approx 10^3 \text{ cm}^{-1}$) is much greater than the crystal field energy ($\approx 10^2 \text{ cm}^{-1}$); this is attributed to shielding of the crystal field by the outer fully filled 5p and partially filled 5d and 6s orbitals. The magnetic behavior in rare earths is like that of free atoms: spin and orbital moments are governed by *Hund's rule* and are a function of the number of inner-shell electrons [12.28].

The value of intra-atomic exchange (1.0 eV) is much larger than that of interatomic exchange (0.1 eV) [12.28], hence the moment per atom is largely determined by intra-atomic exchange interactions [12.28]. Moreover, the origin of long-range fer-

romagnetic/antiferromagnetic order and magnetocrystalline anisotropy is also attributed to interatomic exchange interactions and can be explained on the basis of Heisenberg interactions between two neighboring atomic spins S_i and S_j . The exchange energy is expressed as

$$E_{\text{ex}} = -2J_{\text{ex}}S_iS_j. \quad (12.19)$$

Positive values of the exchange integral J_{ex} favor parallel spin alignment, and negative values favor antiparallel spin alignment. In ferromagnets, such as Fe, Co, Ni, FePt, and $\text{Nd}_2\text{Fe}_{14}\text{B}$ alloys, J_{ex} is positive and all atomic spins are parallel. Antiferromagnets and ferrimagnets such as MnF_2 , CoO, and Fe_3O_4 , however, comprise two sublattices having antiparallel moments. If the moments of the two sublattices cancel each other leaving no net moment, antiferromagnetism results, while in a ferrimagnet there is a lowering of net moments. Disorder in magnetic moment due to thermal effects competes with interatomic exchange forces. At a temperature, defined as the Curie temperature T_C , thermal disorder exceeds exchange forces and the ferromagnet behaves like a paramagnet (Fig. 12.2).

Another intrinsic magnetic property, the magnetocrystalline anisotropy, is also of atomic origin. The interaction of L – S coupling with the local crystal field energy determines the shape and orientation of the charge density and is the origin of magnetocrystalline anisotropy. Due to shielding effects, the

rare-earth 4f orbital has strong spin–orbital coupling and hence high magnetocrystalline anisotropy compared with 3d transition metals. These atomic-scale phenomena (magnetization, exchange, and magnetic anisotropy) are significantly modified by nanostructuring [12.28].

12.3 Magnetic Length Scales and Origin of Nanomagnetic Behavior

The fundamental length scales which govern the magnetic properties are the domain wall width δ_m , exchange length L_{ex} , and magnetostatic length L_s . These length scales are determined from the competition between internal magnetic forces [12.29]. Competition between exchange energy and magnetocrystalline anisotropy energy defines the domain wall width $\delta_m = \sqrt{A_{\text{ex}}/K}$. Competition between the exchange energy and magnetostatic energy defines the exchange length $L_{\text{ex}} = \sqrt{2A_{\text{ex}}/\mu_0 M_s^2}$. The magnetostatic length is $L_s = \sqrt{A_{\text{ex}}/2\pi M_s^2}$.

Here, K is the bulk magnetic anisotropy constant and A_{ex} is the exchange constant within a grain. The magnetic properties of a material are dominated by the shortest characteristic length. Some of these characteristic length scales are given in Table 12.1; it is evident that the dimensions of nanostructured magnetic materials lie in the range of relevant characteristic lengths; hence these materials are considerably influenced by nanoscale interactions such as exchange and Ruderman–Kittel–Kasuya–Yosida (RKKY) interactions.

12.3.1 Domains in Fine Particles

Due to the dramatic change in magnetic properties compared with their bulk counterparts, nanoparticles are of great research interest for engineering applications. Two important aspects of nanostructured magnetic materials are single-domain particles and superparamagnetism [12.30]. The key difference between bulk and

single-domain particles is the magnetization reversal mechanism; in single domains, reversal takes place via coherent rotation and maximum coercivity is observed. In the single- to multidomain transformation there is magnetostatic energy minimization, hence the critical radius of a single-domain particle is determined by the balance of domain wall energy and magnetostatic energy as

$$R_c = \frac{36\sqrt{A_{\text{ex}}K_{\text{eff}}}}{\mu_0 M_s^2}, \tag{12.20}$$

where A_{ex} is the exchange constant, M_s is the saturation magnetization, and K_{eff} is the effective anisotropy. For many magnetic materials, the single domain size is ten to a few hundred nanometers [12.9, 30]. If single-domain particles become small enough that the thermal energy exceeds the anisotropy energy (e.g., $k_B T \ll KV$), the magnetic moment fluctuates from one easy direction to another. This phenomena is termed superparamagnetism. This thermal switching frequency is explained by the Arrhenius–Neel equation

$$\tau = \tau_0 e^{KV/(k_B T)}, \tag{12.21}$$

where τ is the magnetization switching frequency, τ_0 is a proportionality constant (10^9 s^{-1}), k_B is the Boltzmann constant, and T is temperature. Superparamagnetism is characterized by zero remanence, zero coercivity, and a blocking temperature (T_B) below which ferromagnetic order reappears. For $k_B T \gg KV$, the system behaves like a paramagnet. Single-domain

Table 12.1 Magnetic characteristic lengths (after [12.29])

Domain size (nm)	$10\text{--}10^4$
Domain wall width (nm)	$\approx 1\text{--}\approx 10^2$
Exchange length (nm)	$\approx 1\text{--}\approx 10^2$
Exchange interaction range (nm)	$\approx 10^{-1}\text{--}\approx 1$
Superparamagnetic diameter (nm)	$\approx 1\text{--}\approx 10^2$
Ruderman–Kittel–Kasuya–Yosida (RKKY) interaction length (nm)	$\approx 10^{-1}\text{--}\approx 10$

particle magnetism plays an important role in magnetic recording. The thermal stability limit for magnetic recording is $KV > 25k_B T$ [12.31].

12.3.2 Nanomagnetism

The phenomena that cause nanomagnetic properties are:
